With reference to the symptoms in these cases: I think the most important are straining, bloody dejections and the absence of natural alvine evacuations. Ordinarily a tumor can be detected, such, at least, is my experience.

DR. A. M. CARTLEDGE: The only case of obstruction of the bowels that I have seen in the young child occurred in a little girl three years of age and was volvulus. The only case of invagination I have seen in a surgical way in the adult occurred in a young man in Indiana about a year ago. I exhibited the specimen and reported the case at some length before this society at the time. The invagination was at the ileo-cæcal valve and was about eight inches in extent. I resected the invaginated mass and made an end to end anastomosis, but necrosis and gangrene had taken place at the time of the operation and the patient died three hours afterward.

DR. A. M VANCE: I have never performed a laparotomy for intussusception, although I have seen several cases in which operation has been advised by others. I was recently called to see a child five months old reported to be suffering from invagination; I did not think operation advisable in the condition in which I found the child. The child died the day following. It is a wonder to me that invagination does not occur oftener, when we consider the tremendous suction power of the intestine. I have demonstrated this a great many times in operating upon dogs in endeavoring to make an end to end anastomosis. In approximating the afferent and efferant ends, the afferent would sometimes be sucked into the lower and requiring considerable force to bring it back by the suture attached. I can understand readily how when invagination starts it would be carried right along by the sucking power of the intestine, the bowel above contracting and the muscular coat relaxing below forcing the intussusceptum downward very rapidly. In making an end to end anastomosis upon dogs I have often inserted my finger into the end of the lower portion of the intestine and the suction and contraction is so great as to make it perceptibly painful.

My experience is that babies particularly stand abdominal surgery very badly. I think the percentage of deaths would be more than double as compared with people who are older.

DR. C. SKINNER: I do not think all cases of appendicitis should be condemned

to the knife, but do believe that all cases of intussusception belong to the surgeon.

DR. H. A. COTTELL: As I stated before a recent meeting of this society, in discussing ths question of appendicitis, the only case of intestinal obstruction, which was probably appendicitis never made out, that I had seen which proved fatal occurred in the person of a child two years of age. We had the counsel of several eminent physicians and at least one eminent surgeon. The case was decided non-operable, the opinion being based upon the extremely tender age of the patient. I am satisfied, however, that a case in the hands of Prof. Anderson or Prof. Roberts would get all the chances of life that science could give it. I doubt if operation on any patient of such a tender age could be done with any reasonable hope of success.

DR J. A. LARRABEE: It has been my fortune—or misfortune, I take it—to have seen quite a large number of cases of intussusception. In looking back over my practice I can recall by name thirteen cases, 12 deaths and one attempt at recovery. One of them came very near being a repetition of the very strange case referred to by Dr. Roberts to-night. A negro child that lived three weeks after sloughing of the intestine, then died of perforation.

One point mentioned by Dr. Anderson in regard to these cases has been borne out by my experience, i. e., the diagnosis is not as difficult as it might at first present. It is a little strange that earlier diagnosis is not arrived at when we take into consideration the facts already recited to-night. The history of these cases is that they are always of sudden occurrence; next, the peculiar facial expression—Dr. Anderson has alluded to that, and I consider it one of the best points made in connection with the subject—there is not as much pain as is manifest in ordinary colic, but there is never a case without that peculiarity of expression which he has so correctly described. Again, I have never seen a case in which I was not able to make out a sausage-like tumor, except one. This occurred in a child suffering with an attack of varicella; intussusception came on without any cause, and like most such cases occurred suddenly at, or immediately after, straining at stool.

Dr. Vance has brought up a very significant fact in this connection, viz.: the suction of the intestine; when the intussusceptum once gets started it is carried on by this suction. Most of the cases I have seen have occurred immediately after efforts at stool. As I have already stated the diagnosis in my experience has been comparatively easy; I have never made more than two visits before satisfying myself as to the diagnosis. As Dr. Skinner has very correctly said, these cases are strictly surgical just as soon as they are diagnosticated, and with the power of making early diagnosis, with the facts against its being anything else, either in the very young or the very old, I think the surgeon ought to be employed very early. I am a little surprised to hear Dr. Vance say that babies stand abdominal surgery so badly; I did not know that the operation was attended with such fatal results. I think the hope we have for relief by means of surgery is greater than by medical treatment; in my experience five days was the limit of life in these cases treated medically.

DR. W. L. RODMAN: I think the relative frequency of intussusception in children is clearly due mostly to anatomical reasons; due to the same cause which makes hernia so very common in young children. In early childhood the mesentery is nearly twice as long relatively as it is in the adult; this same mesentery becomes again elongated in older subjects. This to my mind explains the comparative frequency of intussusception and hernia in the young, and in advanced age.

I fully agree with the position taken by Dr. Roberts as to the treatment. I feel that the importance of surgery in these cases cannot be over-estimated. While enemata may relieve a few cases in the very early stage of the trouble, and I think it should be always tried, just as taxis should always be tried in early strangulated hernia, I am satisfied that it should be tried no longer than taxis in hernia, and should the enemata fail to relieve the case very promptly I am thoroughly satisfied that the case demands early laparotomy. I therefore agree with the essayist that most of these cases call for a laparotomy, though they should certainly be treated medically at first. I hardly believe that the morality is as great as statistics would make it appear. If the cases could be seen and operated on as

early for instance as in strangulated hernia, I think the results would be very much better than they now seem to be. Certainly nature will do less for these cases than obtains in strangulated hernia, therefore early laparotomy for relief of the intussusception is demanded, and when the operation is done early in the attack I believe results will be more favorable.

TUMOR OF THE MAMMARY GLAND—OPERATION.

DR. W. L. RODMAN: This specimen is the left mammary gland removed from a young woman, married, twenty-seven years of age, kindly referred to by Dr. Goslee of Carrollton, Ky. She gave the history of having borne one child aged three years, which was nursed for eighteen months. Shortly before Christmas last she noticed a small hard lump about two inches above the left nipple. It was painful from the first, but grew more so gradually. Her general health I may say was not good, and an examination of her urine showed quite a perceptible amount of albumen. This made me hesitate as to whether or not I should remove the tumor, but, on account of the fact that it was causing her considerable pain, and the mental distress was very great on account of the presence of the growth, I thought it wise to remove the gland. I did so one week ago last Wednesday, removing the entire organ, as I believe that to be the only treatment for any form of neoplasm of the breast whether benign or malignant. I may say that I thought before the operation that this tumor was probably benign, notwithstanding the fact that she had complained, of considerable pain. It has not yet been microscopically examined, but this will be done in the course of the next few days and I will make a further report. I take it to be a fibroma. Fibromas of the mammary gland are sometimes attended with pain, just as they are in other situations. The axilla was not invaded as I thought the growth was begin. The mammary gland was removed in its entirety an elliptical incision eleven or twelve inches long being made. In changing the dressings yesterday I found that the wound from end to end had healed completly without a single drop of pus. I gave chloroform and administered a very small quantity of it, removing the breast very rapidy so as to not damage the kidneys more than they already were.

DISCUSSION.

DR. H. A. COTTELL: Cases of neoplasm of the breast are always interesting to me, because of the fact that the first case I ever saw, which occurred fitteen years ago in the practice of Dr. E. R. Palmer, in the person of a darky girl, doth breasts enormously enlarged. Under treatment non-surgical those breasts were soon reduced to the normal condition. I remember the case very distinctly, and know the darky to-day and she has raised quite a family of children. The condition was always a mystery to me. The mammary glands are normal to-day. Of course we may have any sort of neoplasm of the breast—sarcoma, carcinoma, epithelioma, endothelioma, etc., and we may have fibroma, adenoma or simply an inflammatory condition which we may call hyperplasia. A great many cases of mammary tumor which are condemned to the surgeon's knife I am satisfied are simply the result of an inflammatory action following an abscess.

The worst case of neoplasm of the breast that I ever saw, which progressed most rapidly, which proved to be malignant, returning after operation to destroy the woman's life, was under the microscope purely an adenoma; under the most careful examination it was impossible to make out any species of cancer.

While we are on the subject of carcinoma, etc., I recall some statements I made seventeen years ago which will bear a repetition: When you come to the question of cancer, you are never sure that the tumor you are dealing with is malignant or non-malignant in character until you can demonstrate infiltration into the surrounding structures. For instance you take a pure epithelioma beginning in the rectum, or cancer of the bowel, and it is to all intents and purposes a normal structure until it has broken loose and begins to infiltrate into the surrounding structures. It is a common thing in demonstrating pure epithelioma, to show students a normal section of the rectum, then afterward show them what is called cylindrical epithelioma, and no distinction can be made until the muscular coat of the bowel, the peritoneum or surrounding organs have been invaded by the disease.

DR. W. L. RODMAN: How many specimens of pure adenoma of the breast have you examined microscopically?

DR. H. A. COTTELL: I do not recall of course the exact number, but perhaps a dozen.

DR. W. L. RODMAN: Gross in his book on tumors of the mammary gland, says that he never saw but one case of pure adenoma of the mammary gland—fibro adenomas are more common. Bryant called them adenoceles.

DR. H. A. COTTELL: If you insist upon *pure adenoma*, it may make some little difference, of course I referred to the cases usually denominated adenoma, and it is a fact that a great many of these cases do occur.

I have a case that I would like to report which as far asmy experience is concerned, is rather unique. A boy aged six years was brought to my office to-day, who in climbing a ladder carrying a bag in a difficult position discovered when he came down from the ladder that he was weak and out of fix. This happened a week ago. He went into the house and told his mother that something had happened to him, that he had hurt himself in some way. She told him to go up stairs and go to bed, that she thought he would be all right shortly. He found it very difficult to get upstairs. In a few hours he came down crawling on his hands and knees. The condition of the boy is peculiar; he has complete paralysis of the left leg, involving the muscles of the hip, muscles of the back below a certain line, below the dorsal region, incontinence of urine; everything below that totally paralyzed. I suppose we would call it *quarto-plegia*—it is not hemi-plegia, and not para-plegia. The right limb is in perfect condition. By the use of electricity the reaction of degeneration is not marked. I report the case because I want some light thrown upon it if possible. I am of the opinion that it is a case of spinal hemorrhage; it is certainly peculiar that it should have so affected the spinal cord. The boy's temperature and pulse are normal. There are no symptoms of any kind except complete loss of both motion and sensation in the left leg, and incontinence of urine. The patient was referred to me by a physician in the country. I suggested that the case be put upon iodide of potassium and ergot for two weeks, with instructions that the result be reported to me at that time. I take it to be a case of limited spinal hemorrhage. We all know very well that certain violent straining exercise, certain things which twist the spinal cord may produce hemorrhage.

Caustics in Malignant Growths.

Of late the tendency seems to be to use caustics in treating certain malignant growths, especially those of the skin and superficial parts. Dr. John Parmenter, in the *Journal of the American Medical Association*, advocates the use of caustics on the ground that recurrence of the growth is less frequent, that caustics have a selective action and that they reduce enlarged lymphatics near the seat of disease. We must use the proper caustic and use it intelligently. Of the various escharotics the author prefers Bougard's or Vienna paste, the composition of which is as follows:

℞

Wheat flour	60 grams
Starch	60 "
Arsenic	1 "
Cinnabar	5 "
Sal ammonia	5 "
Corrosive sublimate	0.50 centigrams
Sol. chloride zinc at 52	245 grams

From his work Dr. Parmenter concludes as follows:

1. The value of caustics in the treatment of malignant disease depends upon the use of proper caustics and their intelligent application in suitable cases.

2. A proper caustic is one which completely destroys and removes the malignant tissue.

3. Mild caustics are inefficient and dangerous, and therefore to be avoided.

4. Bougard's paste is the most generally useful escharotic.

5. Proper technique in application accentuates the value of caustics.

6. The suitable cases are those which have a limited extent and are easily accessible, or in other words, cancer of the skin, lip and external ear, in their incipient stages.

7. The prognosis should be most excellent, cure resulting in the vast majority of cases when treatment is early and thorough.

Small-Pox.

℞

Salicylate of soda	
Antipyrin	āā 5ij
Aq. menth. pip	f3iv
Glycerin	f3j

M. Sig.: Tablespoonful three times a day.

THE LIBRARY TABLE.

BOOK REVIEWS.

An International System of Electro-Therapeutics: For Students, General Practitioners and Specialists. By Horatio R. Bigelow, M. D.; and Thirty-eight Associate Editors. Thoroughly illustrated. In one large Royal Octavo volume, 1160 pages, extra cloth, $6.00 net; sheep, $7.00 net; half-Russia, $7.50 net. Philadelphia: The F. A. Davis Co., publishers, 1914 and 1916 Cherry street.

This work contains the articles of 38 different writers and represents four countries, United States, Canada, Great Britain and France, the great bulk of the writers being American. It is a notable fact that no German author appears in its pages as a contributor.

The whole field of medicine is considered with reference to electricity as a therapeutic agent, and the book is thus divided into sections, A. B. C., etc., the first being occupied with electro-physics and medical apparatus, the second with electro-physiology, etc. Each set of organs of the human body is the subject of electric treatment from the medical as well as oft-times from the surgical standpoint. With the exception of the first, the largest section of the book is the one devoted to gynæcology. It contains 234 pages and gives the electrical treatment for all the diseases of the female pelvic organs from pus tubes and extra-uterine pregnancy to disorders of menstruation. It is in this field that the electrician has engaged in bitterest conflict with the surgeon. The former does admit that there are indications for the use of the knife, but it is not likely that he will be able to persuade the general practitioner to go to the same lengths as himself in the so-called conservative treatment of diseased appendages.

In a work of this character there is of necessity considerable repetition throughout the book; and from the standpoint of a reference book, this is rather an advantage than a disadvantage, for the reader can find what he wants by consulting a single article instead of reading the book as a whole.

The book does not contain new ideas, and it is probable some of the methods there advocated are already antiquated, as must be the case in every advancing science.

It is a matter for congratulation that our knowledge of electricity in a medical sense has been collected and systematically arranged as in this work.

It will no doubt remain for years the standard book for reference on this subject, and should be in the hands of every physician interested in this branch of medicine.

The book itself is well illustrated and neatly gotten up, and does credit to the well-known firm who published it.

A Clinical Manual. By Andrew MacFarlane, A. B., M. D.

This little work contains the directions for making an examination of the urine, feces, blood, stomach contents, and some exudates and pathological fluids, and is intended as a hand-book for physicians and students examining these substances to complete a clinical diagnosis.

A Primer of Psychology and Mental Disease. By C. B. Burr, M. D., Medical Superintendent of the Eastern Michigan Asylum, etc.

In his dedication the author states that his intention was to simplify an abstruse subject, and he seems to have kept this object in view throughout the work; so that it is doubtful if any other book on this subject gives a beginner more practical information in as small space.

Essentials of Diseases of the Eye, Nose and Throat.

This is one of Saunders' series of Question Compends and is the second edition of this number.

The work is divided into two sections—Essentials of Refraction and Diseases of the Eye, by Edward Jackson, A. M., M. D.; and Essentials of Diseases of the Nose and Throat, by E. B. Gleason, S. B., M. D.; and will be found useful to students preparing for examination or for a course in a dispensary where these specialties are treated.

Essentials of Nervous Diseases and Insanity. By John C. Shaw, M. D.

This work is one of Saunders' series of Question Compends, and the second edition which has just appeared, differs from the first mainly in the correction of a few errors. While dealing with the subjects treated as fully as a book of this size could, it is intended as a preparation for the study of one of the larger text books, and as a resume for advanced students preparing for examination. List price $1.00; 48 illustrations and cuts in the text.

Human Physiology. By John Thornton, M. A. Crown 8 vo. 268 illustrations and cuts in the text. Longmans, Green & Co.

This book goes as fully into the subject as teachers in public schools, academies, etc., usually care to, the subject of reproduction and the organs concerned is carefully avoided, and the book being written in a rather easy, interesting style should find favor in the smaller schools, etc.

Essentials of Pharmacy. By Lucius E. Sayre,

is the the title of another of Saunders' Question Compends, now in its second edition. It is intended especially for students of pharmacy, follows the pharmacopœia closely, and the new edition is brought strictly up to date to correspond to the pharmacopœia of 1890.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

VIRGINIA MEDICAL MONTHLY

for September. Dr. Bedford Brown advocates

The Cold Poultice

as a means of reducing pyrexia, when the cold bath or cold pack is undesirable or inconvenient to apply. Boiling water is slowly mixed with constant stirring, with enough flaxseed meal to make a layer a quarter of an inch or less in thickness and about eighteen by twelve or fourteen inches. This is spread uniformly over cotton cloth, covered by another layer and sprinkled with ice water until the temperature falls to 70° or 75° F. It is then applied over the abdomen and chest.

If desired a narrower poultice may be applied over the spine. The author says this acts as a prompt tonic to pulse and nervous system generally, and will reduce a high temperature almost as much as the coal tar antipyretics, and without their depressing effects.

Dr. A. R. Shands gives the result of his experience with the

Treatment of Clubfoot by Wolff's Method.

The method described is the application of rubber adhesive plaster to hold the foot in the best position obtainable at the first dressing. The malleoli and any other bony prominences are now protected by strips of cotton cloth—the whole leg up to the tuberosity of the tibia covered by a double layer of canton flannel bandage, and, finally a couple of plaster of Paris bandages are applied—the limb all this time being kept as much corrected as possible.

Next day over the prominence of greatest deformity a wedge-shaped piece of plaster is removed, two angles being connected by a linear incision around the rest of the plaster casing. The foot is now forced into a position of greater correction and another plaster roller applied (over the first) to keep it so. These incisions are most easily made with a small, fine, handsaw; the blade of which must be dipped in water frequently.

Severe excoriations are apt to result if care be not taken to exclude any fold of skin from slipping between the edges of the cut plaster bandage.

After redressing two or three times, a new dressing must be applied, and the process continued. Finally a position of over correction must be obtained, a small strip of steel incorporated in the final plaster roller, a leather boot applied over all and the apparatus worn for some months.

The author has been well satisfied with his results.

Other papers in this issue are: "Some Remarks on Epilepsy, and the Care of Epileptics on the Colony Plan," by Dr. William F. Drewery; "The Antiseptic Treatment of Infectious Diseases and their Poisonous Remedies Rendered Innocuous," by Oswald L. Schreiner, Ph. L; "Tuberculosis in Animals," by E. P. Niles, D. V. M.; "Difficulty Yet Importance of Recognizing Chancre of the Os Uteri," by Dr. H. R. Coston; "Notes on the Treatment of Diphtheria and Croup," by Dr. R. B. James; "The Prevention of Blindness," by Dr. Benjamin Lee; "Elephantiasis Arabum Cruris," by Dr. Larkin W. Glazebrook.

JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

Drs. J. Abbott Cantrell and Emanuel J. Stout, after quoting several authorities who state that favus may appear on parts of the body free from hair, the palms of the hands, glans penis, soles of the feet, etc., describe a case where large parts of the body were covered by lesions of this disease.

The patient was an Italian immigrant, ten years of age, five feet in height, weighing about one hundred pounds, fairly well nourished.

The whole hairy scalp was affected, the back and sides of the body, outer surface of both arms, left buttock, were affected and smaller lesions on the legs. The mouse like odor was quite noticeable, and a venereal patient on the same floor contracted the disease while this patient was in the house, although proof of direct contagion was not found.

Microscopic examination of a crust confirmed the diagnosis.

Cases reported by other authors are quoted, and the paper will be continued.

Dr. Samuel Sherwell reports a case (still living) of

Ichthyosis Congenita.

A female infant first seen when about one month old. The child was born of American parents, the father of German descent, and has a negative family history. The estimated weight at birth was two pounds, and at that time there appeared to be abnormal coating about one-quarter of an inch in thickness over the body. For about one month the only treatment was free lubrication with olive oil, and a certain amount of improvement has taken place. At first olive oil alone was used; then soft vaseline was added to this, and by gentle friction the outer casing was partially removed.

Baths containing a little borax are used, followed by inunctions, sometimes with cold cream, sometimes mutton fat, etc. The neglect of these for a single day shows very quickly in an increase of the collection on the skin.

The infant is now scarcely seven and one-half pounds in weight.

Dr. Burnside Foster proposes a

New Method of Treating Acute Gonorrhœa.

The author has not yet tried this method, but thinks an early perineal incision, with drainage of the bladder by a tube and anti-

septic irrigation of the urethra from behind offers a speedy cure with sequelæ

Although thinking the adoption of this method would elevate the standard of morals, it is proposed rather as an ideal treatment than as one likely to be eagerly accepted.

Dr. W. H. Brinley makes a

Plea for Rectal Examination in the Diagnosis of Obscure Disease of the Sexual System.

The author thinkt hemorrhoids, even when quite small, rectal ulcers, fissures, fistulæ, and papillomatæ the unsuspected cause of numerous obscure sexual disorders. The removal of hemorrhoids by any other method than excision he thinks crude and out of keeping with modern surgery.

Dr. M. B. Hartzell contributes an article, illustrated with micro photographs, on "The Prolozoalike Bodies of Herpes Zoster."

JOURNAL OF NERVOUS AND MENTAL DISEASES

for September. Dr. W. H. Riley contributes

A Study of the Temperature Sense.

In his investigations the author divided the surface of the body into fifteen areas, and came to the following conclusions. "The parts of the body given in the order of their sensibility are as follows:

1. Abdomen, sacral and lumbar regions of the spine, with the intervening space on each side of the body.
2. Inside of the thigh, chest, cervical spine, and upper dorsal spine.
3. Inside of arm, outside of thigh, lower dorsal spine, and the soles of the feet
4. Front of the neck, inside of forearm, palm of hand, inside of leg and top of foot.
5. Outside of forearm, outside of leg, and forehead.

The soles of the feet are more sensitive than the palms of the hands. The palms of the hands and the back of the hand are about equally sensitive.

Each of the fifteen different areas tested occupied a certain position of its own in the scale of sensibility to heat and to cold, and the parts that were most sensitive to heat were likewise most sensitive to cold.

In every case a temperature of one degree above the surface temperature appeared warm, while one degree below felt cold, but, at least, when test tubes are used, a slight excess of heat is less readily detected than an equally slight diminution (cold).

Water in a test tube and water into which the hand was dipped gave a sensation of cold at about the same temperature; but water at 34° C. felt warm when the hand was immersed, while in a test tube it was necessary to have a temperature of 39° C. to 41° C.

"Contrary to the opinions of Blix and Goldschneider, but in harmony with those of Dessoir, there are not two separate sets of end organs, one for heat and one for cold."

An article by Dr. V. P. Gibney describes a

Non-Operation Treatment of Metatarsalgia.

This trouble seems to be a neuralgia about the head of the metatarsal bone of the fourth toe, and the author reports cases in which he has been able to afford relief without excising the bone.

Patients suffering with this trouble instinctively remove the shoe and press the foot between the hands to obtain relief. Believing that a shoe which would imitate this procedure the author had made for some of his patients a Spanish last (a last made with a high instep) and found that shoes made on this, and fitted with a high heel extending toward the centre of the foot gave great relief to most cases.

Dr. Charles L. Dana reports a case of "Gliomatosis of the Spinal Cord and Syringomyelia with Recurrent Hemorrhages." Dr. W. A. Tomlinson writes of the "Genesis of Hallucination, Illusion and Delusion." Drs. F. X. Dercum and W. W. Keen report two cases of "Ingravescent Cerebral Hemorrhage Treated by Ligation of the Common Carotid." Dr. Livingston S. Hinckley writes of the "Difficulties which Prevent the Realization of Dr. Mitchell's Ideal Insane Hospital."

Methylene Blue in Pulmonary Tuberculosis.

Owing to the recommendation of Dr Althern, of Wiesbaden, Dr. Bronowski, of Professor Tumas's clinic in Warsaw, has employed methylene blue in eight consecutive cases, five of which were in an advanced stage. The remedy was usually given in the dose of 2 to 3 grains (in wafers) three times a day. It was tolerated well by all the patients except one, in whom it occasionally caused sickness. He found that the drug reduced the temperature, but that this effect was much less decided when there was much destruction of lung-tissue. In most cases it diminished night-sweats. In advanced cases it has no effect upon cough, expectoration, or diarrhœa. In incipient cases it may prove of benefit.—*Kansas Medical Journal.*

Benefit to Ear Patients from Nasal Treatment.

Dr. H. Gradle (*Jour. Amer. Med. Association*) says: Acute suppurative inflammation of the middle ear, if not treated has a tendency to become chronic, the tendency increasing with the age of the patient. Chronic suppuration of the middle ear rarely heals without ear treatment. Neither acute nor chronic purulent otitis is influenced by nasal treatment, but the liability to relapses after their cure is decidedly lessened by the removal of naso-pharyngeal anomalies. Acute catarrh of the middle ear will generally terminate in complete recovery under aural treatment, and sometimes even without it, provided there are no persistent nasal or pharyngeal lesions. But when these are present the disease is more likely to become chronic in spite of aural treatment, and in many cases can either not be cured, or if improved, will speedily relapse unless the normal state of the nose and throat is restored. Proliferating or adhesive disease of the middle ear is the consequence of retro-nasal catarrh, and its course is determined by the course of the disorder causing it.—*Toledo Medical Compend.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE

Rheumatism in Children.

M. Jules Simon calls attention to the multiplicity and anomalies of rheumatic manifestation in children. Infantile rheumatism may attack the vertebral articulations, especially in the suboccipital region. Suboccipital arthritis is, somewhat peculiar to childhood. It must be distinguished from simple torticollis and should not be confounded with cervical Pott's disease.

The tendinous sheaths are often involved. They communicate a sense of crepitation to the finger. They feel as if they were filled with starch. The pangs of rheumatic synovitis are often mistaken for growing pains. The latter, however, are very different from those due to rheumatism. They only occur when the growth has been extremely rapid, as within a few days or weeks. Rest in bed causes them to rapidly disappear. Again their situation is very different from that of rheumatic synovitis. For instance, it is behind the knee that children complain of growing pains, while synovitis is located at the sides and in front of that joint.

The tendency to muscular atrophy is very great in children, but this atrophy readily disappears. M. Simon also indicates the frequency of rheumatic angina in children as well as certian gastric disturbances with repeated attacks of indigestion. Diarrhœa, likewise, is sometimes produced by the rheumatic diathesis. Abundant sweating is another manifestation which often depends upon rheumatism. The child's skin is always wet. He perspires profusely even when at rest or during the night. The sweats coincide with a scanty secretion of urine which is charged with urates. M. Simon does not approve of the custom of allowing children to be bare-legged. He is of the opinion that this fashion is a frequent cause of rheumatic manifestations, particularly erythema nodosum of the legs. As an abnormal localization of rheumatism the writer alludes to the occurrence of more or less painful cystitis. He quotes the case of a young girl of rheumatic taint who was attacked every time that she was chilled by a slight soreness of the throat, followed by a cystitis, which caused extreme pain and sometimes retention of urine to such a degree that it was necessary to use the catheter.—*La Medec. Mod. Med. Bulletin.*

A Premonitory Symptom of Phthisis Pulmonalis.

Destree remarks that in the course of pulmonary phthisis one often observes, without any very obvious cause, inequality of the pupils. This phenomenon is not seen in cases of apical pneumonia, or of bronchitis with emphysema, but it occurs in chronic pleurisies of old standing. It has a certain diagnostic value.

Destree made experiments on dogs and rabbits, and found that inequality of the pupils could be produced by irritation of the sympathetic in the thorax. When the nerve was stimulated in the neighborhood of the root of the lung, the pupil of the corresponding side dilated. Autopsies on tubercular subjects frequently show that the root of the lung and fibres of the pulmonary plexus are compressed and irritated by enlarged bronchial glands. Tuberculosis of the bronchial glands may therefore manifest itself by dilatation of one pupil several years before other symptoms set in.—*La France Medicale.*

Headache.

WHEN FROM NASAL STENOSIS.	WHEN FROM EYE STRAIN.
Generally unilateral.	Generally bilateral.
Frequent insomnia, often worse in the morning.	Sleeps soundly; improved after sleep.
Aggravated by physical exertion, as running, stooping, etc.	Aggravated by mental application and using the eyes.
Not subject to conjunctivitis.	Conjunctivitis after prolonged use of eyes.
Generally nasal catarrh.	Catarrh not complained of.
Excited by acute coryza.	Not subject to acute coryza.
Nose not suspected by patient.	Eyes believed to be the cause.
Dyspepsia and nausea.	Appetite and digestion good.
Astigmatic chart test negative.	Same test generally affirmative.
Pressing middle turbinated with probe increases.	Same test negative, except to cause sneezing
	Sensitive to bright light.

—*Med. Brief.*

Relation of the Pneumococcus to the Symptomatology of Pneumonia.

Numerous observers have found this microbe in various parts of the air passages in persons who were, at the time, in perfect health (*Modern Medicine*). Pasteur has discovered it in the pharnyx and neighboring cavities—the nasal fossæ, the frontal sinus, the Eustachian tube and even in the bronchi. Netter has shown it to be persistent for an indefinite time in the saliva of persons who had suffered from pneumonia and had recovered. He also frequently observed it in persons who had never suffered from the disease, finding it present in 20 per cent. of 130 healthy persons who had never suffered from pneumonia. Golding Bird found the germ present in 505 of a large number of healthy persons whom he examined, none of whom had suffered from the disease in question.

Cultures of the pneumococcous lose their virulence about the seventh day. It is also

at this date that a rapid defervesence occurs in pneumonia. The so called "crisis" of the disease corresponds with the loss of pathogenic properties of the germ.

It is also noted that the saliva of the patient, which during the development of the disease is extremely virulent, producing pneumonic infection in animals when introduced by inoculation, loses its virulence about the seventh day.

The pneumococcus rapidly loses its virulence under the influence of a temperature of 40° C. (104° F.), and loses all activity when submitted to a temperature of 42° C. This fact coincides with the loss of pathogenic properties which the microbe undergoes under the influence of the high temperature which attends the developing of stage pneumonia.

The pneumococcos does not die, however, at the critical period of the disease, but only temporarily loses its virulence, reacquiring its activity at the end of fifteen or twenty days. This reacquired violence may be retained indefinitely while the microbes reside in the mouth of the recovered patient.

Diet for Typhoid Fever.

Perhaps the best of all diets in typhoid fever is kumyss. The lactic acid which it contains will prevent the growth of the typhoid bacillus. The finely divided state of casein prevents the formation of curds. The carbonic acid is soothing to the irritated condition of the mucous membrane; the taste is grateful to the patient; the acidity stimulates the secretion of the gastric juice, and thus aids digestion—in fact it seems to fulfill all the requirements of a food specially suited to the condition of a typhoid patient or a patient suffering from any serious febrile disorder.—*Ed. Mod. Med.*

Elephantiasis Syphilitica of the Lips.

In a case described by Professor Elchhorst (*Virch. Arch.*) a man, æt. forty-three, was attacked five years after the primary affection by a peculiar, diffuse, soft swelling of the lips, producing considerable deformity. Every form of local treatment proved futile. The lower lip, however, was successfully treated with galvano cautery, but two months later swelling of the testes set in. This subsided under pot. iod. treatment. The swelling in the lips then recurred, but was gradually reduced by inunction, only to reappear again after a little time. The patient was finally discharged uncured.

Introduction of Syphilis into Europe.

According to Professor Binz (*Deutsche med. Woch.*) syphilis was undoubtedly first introduced into Europe from America, and it is to the sailors of Christopher Columbus' first expedition that we owe the "malady of France," as Shakespeare has it. Nothing pointing definitely to true syphilis can be found amongst the records of either Jews, Egyptians or Greeks, nor even the writings of the satirists of Imperial Rome. The latter, it is true, contain descriptions of gonorrhea and the local sore, but no mention is made of the sexual infection spreading over the whole body, becoming constitutional in fact. All authorities, however, agree that in 1495 lues venerea became epidemic in Europe, and subsequently spread over the whole world. Dias de Isla, a physician of Barcelona, states that the malady was imported by the companions of Columbus. During 1494 it was carried into Italy by the armies of Charles VIII, and from Italy it was spread over Europe. Oviedo and Las Casas, contemporaries of de Isla, bear confirmatory evidence.

A critical examination of the works of the authors mentioned will demonstrate their unreliability. Buret's analysis is certainly convincing, and English readers will soon have the opportunity of reading the translation.

Tuberculosis in Childhood.

Goldschmidt reports cases in which the infection was probably of intra-uterine origin. 1. In the lungs of a child aged sixteen months, there were numerous broncho-pneumonic foci and many miliary tubercles. The bronchial, mediastinal and mesenteric glands were enlarged, and the last named caseous. The other organs were intact. On the under surface of the liver, and shining through the peritoneum covering the longitudinal fissure at the entrance of the lig. teres there was a mass of the size of a pea, proved both microscopically and bactereologically to be tuberculous. 2. In the lungs of a child, aged seven months, there were numerous tuberculous nodules, some of which were partly caseous, as well as cavities varying from the size of a pea to that of a hazel nut. In one as large as a walnut, with the thinly purulent contents, tubercle bacilli were demonstrated. There were also numerous intestinal ulcers. At the entrance of the lig. teres there was also a tuberculous mass, and no other tuberculous foci were found in the liver. 3. The infant of a woman subsequently dead of advanced tuberculosis was removed from its mother immediately after birth. It died, when nine weeks old, of atrophy. Numerous large tuberculous nodules, here and there caseating, were found in both lungs, and miliary tubercles in bronchial glands, in the liver, spleen and kidneys. The mesenteric glands were caseous. The tuberculous lesions were here unquestionably of longer duration than the infant's extra-uterine life.—*British Medical Journal.*

Methyl-Blue for Epitheliomata of the Face.

M. Darier reports favorably of this treatment, which he has employed successfully in a series of nine cases. In superficial cases he touches the diseased surface once daily with a 1-to-20 solution. Preliminary cauterization hastens the cure. The drug seems to have a specific action upon the cancerous tissue. If the tumor is deeply seated he uses hypodermatic injections, and if there is extended ulceration skin-grafting is recommended.—*La Tribune Medicale.*

Trional in Delirium Tremens.

Dr. Russell Bellamy, in treating ten cases of delirium tremens with trional, a new hypnotic, records the results of his work in the *New York Medical Journal*, as follows:

1. Delirium was controlled with greater rapidity and safety by trional than by other hypnotics.
2. In the majority of cases a marked stimulant effect was observed, possibly on account of the methylic and ethylic elements which enter into the composition of the drug.
3. On account of the low temperature noted in all cases, trional must possess antipyretic properties, thereby simulating its allies of the phenol group.
4. It was always well borne by the stomach, and in one case was rapidly absorbed when administered per rectum.
5. No unpleasant after-effects were observed, and in all cases, except one, and a tuberculosis complication, recovery was very speedy.—*Maryland Medical Journal.*

Self-Infection in Child Bed.

F. Ahlfeld, in a paper published in the *Zeitschrift f. Geb. und Gyn.*, reaches the following conclusions:

1. The occurrence of fever in child bed, originating without previous examination, cannot longer be doubted.
2. These fevers are, for the most part, unimportant, though severe and even fatal cases are probable.
3. In well-conducted institutions the number of fever cases resulting from self-infection in child-bed is larger than those caused by infection from without. The latter, however, are usually of a severer type.
4. The percentage of morbidity and mortality in an institution in which due care is taken to prevent infection from without, depends on separating the primiparæ from the multiparæ and on the number of operative cases.
5. Preliminary disinfection of the birth canal is an important prophylactic measure.
6. Sublimate remains the best disinfectant.
7. The seat of infection is generally not the external genitals, but rather the cervix and endometrium.
8. Most fever cases in child-bed are to be considered as resorption fever. They result principally from retention of the infectious child bed secretions.
9. The seat of most active absorption is the uterine mucosa; next that of the vagina.
10. The poison taken up is, as a rule, promptly eliminated—probably through the urine.
11. Pathogenic microorganisms are always to be found in the vagina. They need only a favorable culture medium to develop their activity. This they find in the decomposing contents of the vagina and uterus after labor. *Brooklyn Medical Journal.*

The Influence of Oophorectomy on the Voice.

According to an account given in the *Progres medical* for May 5, Dr. Moure, of Bordeaux, stated at a recent meeting of the *Societe francaise d otologie* that in two women who had undergone this operation he had observed that the voice had become strong and coarse. One of them, who had originally had a soprano voice, had lost her high notes and almost become a contralto. The laryngoscopical examination had not shown any anomaly of the vocal organs. Dr. Moure asked if such disturbances of the voice might not be attributed to elongation of the vocal bands or to a more considerable development of the thyroid cartilage.—*N. Y. Medical Journal.*

Tight Lacing and Gallstones.

Prof Marchand, of Marburg, a few years ago called attention in the *Deutsche Medicinische Wochenschrift* to the fact that gallstones and tight-lacing are frequent coincidents. According to Dr. Marchand, the relation of tight-lacing to the development of gallstones is rendered very clear by noticing the situation of the gall ducts in the liver deformed by tight-lacing. The furrow caused by lacing runs directly across the right lobe of the liver, as the result of which there is a tendency to atrophy of the gall bladder. When tight-lacing has been practiced to an extreme degree, an artificial fissure is formed in the liver, giving rise to what is term the "lacing-lobe," which carries with it the gall bladder. The constricted portion of the liver is found to be just at the point of junction of the gall bladder with its duct. In these cases, according to Professor Marchand, it is common to find the gall bladder greatly distended, extending far beyond the border of the liver, and frequently an examination made post-mortem reveals the presence of gallstones.

Stagnation of the bile is well known to be one of the most important causes of the formation of gallstones. A change in the composition of the bile, from catarrh resulting from congestion of the mucous mebrane and the thickening of the bile due to failure of the gall bladder to completely evacuate itself, gives rise to the formation of small masses which serve as nuclei for calculi; hence anything which obstructs the free outflow of bile through the cystic duct, must favor formation of gallstones.

Marchand is also of the opinion that many cases of cancer of the liver should be attributed to tight-lacing. It is only a few years since Langenbuch was obliged to open an abdomen to remove a "lacing lobe" of the liver which had been so completely separated from the rest of the organ as to cause its death, rendering its removal necessary.

In view of such facts as these, is it not the duty of every physician to take special pains to warn his patients against the evil effect of this pernicious practice? Few women are conscious of the fact that they are injuring themselves by tight-lacing, and yet at least ninety-nine out of every one hundred women in the United States are addicted to this evil practice in some degree.—*Ed. Modern Medicine.*

SURGERY.

Landmarks of the Digestive Tract.

Dr. F. B. Robinson (*Mathew's Medical Quarterly*) says:

1. The sigmoid flexure is a very apt location for disease to arise. In dissecting infant cadavers I find the sigmoid very long and often lying in the right iliac fossa. In one infant, about six months old, I found a volvulus of the enormous sigmoid. The sigmoid and rectum are inseparable. In the sigmoid 60 per cent of volvulus occur, and men have volvulus four times as often as women. I was unable to produce a permanent volvulus in experimental works on dogs' bowels. When I stitched it the volvulus would unwind, tear out the stitches or lengthen the pedicle. The cause of volvulus is (*a*) fatless, (*b*) elongated mesentery, and (*c*) a history of constipation.

The peculiar disease to which the sigmoid is liable is stricture (malignant or nonmalignant.) Seventy per cent of strictures of the large bowel occur in the descending colon; and this would give a large number to the sigmoid, as the sigmoid is some fifteen inches long, and the descending colon proper is only eight inches long. No doubt the frequent stricture of the sigmoid is due to (*a*) the sharp and hard foreign bodies which lie on the surface of hard fæces, aud (*b*) the mechanical difficulty of passing through the long, curved gut. A curious feature about man is the sigmoid curve and the rectal ampulla, which must represent some ancient evolutionary stage. A peculiar feature I have long noted in autopsies is that the sigmoid and descending colon are frequently more contracted than the other portions of the large bowel.

2 The splenic flexure of the colon is peculiar from being the most fixed and most acute flexure of the digestive tract. It is held firmly in position by the costo-colic ligament. The sharpness of the bend in the colon at the spleen offers considerable mechanical difficulties to the passage of hard fæces, and this accounts for both malignant and nonmalignant srtictures at this point.

Rough, hard fæces wound mueous membrane and allow infection to travel through the gut-wall into the peritoneum, and this wound kept constantly irritated results in inflammation or malignant growths. The inflammatory products organize into connective tissue, ending in contraction or stricture. Tumors and strictures are difficult to diagnose in the splenic flexure, as they are very high under the ribs, and in laparotomy for intestinal obstruction are often overlooked.

3. The hepatic flexure does not give rise to much intestinal disease. It is not an acute flexure, but possesses a very large angle. Its main difficulty is that it is near the gallbladder, which frequently gives rise to inflammation, and it spreads to the hepatic flexure. It is held to the liver by the hepatocolic ligament. Besides being an obtuse flexure, the fæces are not so solid as they are in the splenic and sigmoid flexures.—*American Lancet.*

Iodoform Oil in Tuberculous Joints.

De Vos (*Centlblt. f. Chirurg.; Am. Med. Bull.*) recommends, after repeated experiments on the cadaver, the following as the points of election for injecting the various joints:

1. SHOULDER.—The arm is adducted, the forearm being bent at the right angle across the abdomen, and the needle is introduced one centimeter behind and below the tip of the acromion process.

2. ELBOW.—A point on the outer side of the olecranon, the needle going in between this process, the radial head and the capitellum humeri.

3. WRIST.—On the radical side of the dorsal edge of the styloid process; on the ulnar side at upper edge of the pisiform bone.

4. HIP.—A line is drawn from a point the breadth of the patient's thumb external to half way the distance from the anterior superior spine of the ilium to the pubic spine. From this point another is drawn to the outer edge of the trochanter major. At the junction of the outer and second fourths of this line the needle is introduced, provided the limb is extended, the foot vertical and the trochanter in its normal relation to Nelaton's test line.

5. KNEE—On the angle between the upper edge of the tibia and the ligamentum patellæ.

6. ANKLE.—Immediately in front of the tip of the external malleolus, the needle being pushed between the astragalus and the malleolus.

Injections are to be made very slowly, not more than 10 cm. in five minutes. As to the dose, one gramme of iodoform (10 per cent. to 20 per cent. emulsion) is sufficient for adults to begin with. This is repeated in a week if no reaction follows, and then every fourteen to twenty one days, the iodine in the urine and persisting tender points being the guide.

In the after-treatment massage and passive motion are to be avoided, but moderate active movements are allowable. Several cases of intoxication were observed. Iodoform oil is considered far preferable to conbinations of the drug with ether or glycerine. The duration of treatment varied from 9 to 325 days, the injections from one to twenty, and, as a result, 72 per cent. were cured, the ultimate results being better than those following erasion or resection.

Ingrowing of Nail.

Ingrowing nail, or *ongle incarne*, as the French call it, is, as is well known, a very painful affection, and unfortunately the operation necessary for its cure is often dreaded by the patients, although local and general anesthetics are employed to render the avulsion as painless as possible. A very simple method has been frequently employed by a

confrere with constant success. It consists in painting the offending portion of the nail with a warmed 40 per cent. solution of caustic potash. In a few seconds the upper horny layer is rendered so soft that it can be easily removed by a piece of broken glass used as a scraper. The application of the solution and scraping are continued until nothing but an exceedingly thin portion of the nail remains, which can be easily removed by a small scissors. The patient can now be considered as cured, without having lost a drop of blood nor felt any pain.—*Paris Cor. Medical Press and Circular.*

Nerve Suturing.

Dr. De Forest Willard (*International Medical Magazine*) says:

Functional restoration is possible.

The closer the apposition the more speedy and complete will be the restoration.

Union is accomplished chiefly by the reaching out and development of nerve fibres from the divided proximal end, these fibres pushing their way across the connecting link of fibrous tissue. The fan-like projection of these fibres is marked in each case.

Engrafted nerve-tissue or flaps cut from the nerve may serve as a framework for new tissue, or may produce embryonic nerve-fibres capable of assisting in reunion.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM SEPTEMBER 9, 1894, TO SEPTEMBER 23, 1894.

Leave of absence for twenty days, to take effect upon the arrival at Fort Schuyler of a medical officer to relieve him, is granted to Captain W. W. Gray, Assistant Surgeon.

Major Peter J. A. Cleary, Surgeon, is relieved from duty at Fort McPherson, Ga., to take effect upon the expiration of his present leave of absence and ordered to Fort Brown, Texas, for duty, relieving Captain William B. Davis, Assistant Surgeon. Captain Davis, upon being relieved by Major Cleary, will report for duty at Fort Brady, Mich., relieving Captain Paul Clendenin, Assistant Surgeon. Captain Clendenin, upon being relieved by Captain Davis, will report for duty at Fort Warren, Mass.

So much of the ordinary leave granted First Lieutenant William F. Lippitt, Assistant Surgeon, as is embraced in the period from August 10 to September 25, 1894, is changed to leave of absence on Surgeon's certificate of disability.

Major Charles Smart, Surgeon, and Captain Harry O. Perley, Assistant Surgeon, are detailed as delegates to represent the Medical Department of the Army at the twenty-second meeting of the American Public Health Association to be held at Montreal, Canada, September 25th to 28th, 1894.

Leave of absence for one month, to take effect after termination of present field duty at Raton, N. M., is granted Major James P. Kimball, Surgeon U. S. Army.

Captain Charles E. Woodruff, Assistant Surgeon, is relieved from duty at Fort Assiniboine, Montana, and ordered to Fort Sheridan, Ills, for duty, relieving Captain Francis J. Ives, Assistant Surgeon.

Captain Ives, on being relieved by Captain Woodruff is ordered to Plattsburg Barracks, N. Y. for duty, relieving Captain Harry O. Perley, Assistant Surgeon.

Captain Perley, on being relieved by Captain Ives, ordered to Baltimore, Md. for duty as Attending Surgeon, and Examiner of Recruits, relieving Captain Louis W. Crampton, Assistant Surgeon.

Captain Crampton, on being relieved by Captain Perley is ordered to Fort Meade, South Dakota, for duty.

Captain Edward C. Carter. Assistant Surgeon, is relieved from duty at Vancouver Barracks, Washington, and ordered to Fort Buford, South Dakota, for duty, relieving Captain Aaron H. Appel, Assistant Surgeon.

Captain Appel, upon being relieved by Captain Carter will proceed without delay to Fort Ethan Allen, Vermont, and report for duty at that post.

The leave of absence for seven days granted Captain C. N. B. Macauley, Assistant Surgeon, is extended twenty three days.

Leave of absence for twenty-one days, to take effect about September 20. 1894 is granted Captain William. P. Kendall, Assistant Surgeon.

The leave of absence for seven days, granted Captain Louis Brechemin, Assistant Surgeon, is extended twenty three days.

Leave of absence for one month is granted Major Henry M. Cronkhite, Surgeon.

NEWS AND MISCELLANY.

Twenty-Fifth Annual Session of the Medical Society of Virginia to be Held in Richmoud, Va., Beginning October 23d, 1894.

First meeting at 8 P. M., Tuesday, October 23d, 1894, in Hall of Y. M. C. Association, Main and Sixth streets. Fellows, delegates and members by invitation must register their attendance at the registration desk in the hall of meeting.

All subsequent meetings of the Session will be held in the Hall of the Chamber of Commerce, Main and Ninth streets

The Medical Examining Board of Virginia as at present constituted, will hold its last session for examination of candidates for license to practice in Virginia in the Hall of the House of Delegates, beginning *promptly* at 9 A. M. Tuesday, October 23d, 1894. The board itself will meet in the same Hall at 8 P. M. Monday, October 22d, for business. All letters with reference to this board, and the examinations should be addressed to the secretary of the board, Dr. Benjamin Harrison, Franklin and Seventh streets, Richmond, Va.

LANDON B. EDWARDS. M. D.
Recording Secretary, etc. (for executive committee).

Richmond, Va., 22d, 1894.

THE CARE OF PREGNANT WOMEN.*

WILLIAM B. DEWEES, A. M., M. D., SALINA, KAN.

The study of the diseases and difficulties encountered with a state of pregnancy and parturition, though highly interesting and having at all times attracted the greatest attention of physicians, is, however, exceedingly difficult. This circumstance probably atones for the fact that our obstetrical literature still continues to be full of errors. By consulting the best practical writers, missionaries, and travelers, the revelation comes that it is among the higher classes in the more civilized countries—Europe and North America—that women suffer the greater in both pregnancy and parturition; but that the women of the peasantry and the savage are comparatively exempt. We may therefore very naturally and wisely conclude that it is unnatural for civilized woman to suffer so universally as she does to-day; and that civilization in disobedience to the law of Nature, is the true cause of her present suffering during gestation and childbirth.

It is ignorance, as well as carelessness and viciousness, that has brought about the existing abnormal condition of civilized women. Thus, through unwholesome civilization have come fixed habits of excesses; and if excesses must be indulged, evil consequences will follow and must be endured; for Nature's law would have to be changed before they could be either prevented or banished by any method of treatment. It follows, then, as a natural consequence that to prevent these sufferings will depend, not so much on treatment by application or administration of therapeutic agents, as on the successful education and training of these women, so that they will learn to know how to—and will actually—cultivate the necessary self-discipline requisite to enable them to prevent the continuous irritation from excesses in their modes and habits of life. If the writer's observations have been correct and unprejudiced, it seems that a revival of learning in obstetric science must needs be instituted among us, destined to find the true cause or causes of the unnatural and needless suffering of civilized women. The progress of obstetrics in the immediate future must be made through the knowledge that will be wrought out by the devotees of biology. Thus, we shall find our way, on positive ground back through the morphology of organs, tissues, cells and blood, to a clear comprehension of the origin of vital activity in protoplasm and the pabulum which sustains it. This is the only way open for us into the primitive arcana of nature, if we would have the wisdom essential to intelligently inculcate that regimen which will sucessfully prevent the needless sufferings of pregnant and parturient women.

* Read before the American Association of Obstetricians and Gynecologists at its Seventh Annual Meeting, Toronto, Canada, September 19, 1894.

The future distinction of obstetric science can obtain only by an advanced study of human biology. When this truth is propounded, there opens before the thinking mind a vista so transcending all ordinary limitations of obstetrical knowledge, as requires such genius and expansion of the mental eye in order to embrace it in its simplicity as scarce yet obtains. It remains, then, for our guild, to endeavor by rigid scientific investigation through advanced biologic studies, to make patent the causes of the sufferings of pregnant and parturient women, and to determine exact measures for emasculating these causes, or for neutralizing their effects whenever they have eluded detection or escaped emasculation. Thus, by directing our studies chiefly in relation to etiology and diagnosis, and having learned to know the true cause it will become easy to intelligently establish prevention; while, with a correct diagnosis, treatment will become easy.

I verily believe that the next coming great advance in this, our special branch of medical science, will be in our bringing home to the general practitioner the fact that the diseases peculiar to women during pregnancy and parturition are very largely preventable; to make him feel his responsibility, both as to their production after the present generally prevailing methods of practice, and also as to the possibilities of their prevention after improved methods. The family physician must be fully aroused to the conscious realization of the fact that it lies within his power very largely to prevent many of the diseases among the women of the families intrusted to his care. When this obtains, his moral obligation will impel him to promptly do his full duty, by giving adequate instructions concerning the ill effects of improper posture, dress, food, drink, and erroneous habits of living, including the non-forbearance of indiscriminate, excessive and impure sensual indulgences. Then it will come to pass that the wholesome forbearance of coitus during the entire period of gestation, the puerperium, and three months thereafter, will be insisted upon; together with correct posturing and dressing, proper food and drink, and healthful habits of living. Aseptic accouchments will be faithfully and efficiently practiced; lacerations of the cervix and perineum will be more frequently prevented, and when they do unavoidably occur will be early repaired; rectal and vesical troubles will be corrected in due season; gonorrhea and syphilis will be also more frequently prevented, and when encountered will be more vigorously treated and kept under surveillance until all discharge and sequela are arrested. And, what will be of far greater benefit to mankind, there will be given the requisite attention to the growing girls, with special care about the years of puberty, that more vigorous bodies and more normal reproductive organs be developed. A positive, clear and convincing protest will be made against the present unwholesome state of society which is now urging our girls on to a degree of emasculated physical corruption, by luxurious indolence, deleterious dress and sensual excess, and superbly fits them to live in communities by themselves—in women's hotels—whereby they become ruined for wifely companionship and sturdy maternity. When that day comes —as I verily believe it to be within the province of our intelligence to successfully inculcate—then, and not until then, may we hope to find that the prevalence of diseases among civilized women will cease to be a reproach to preventive medicine. Then will authors and teachers find it necessary to discontinue defining woman as "an animal with a constipated bowel and a pain in her side."

But as yet, at present we are compelled to meet the situation as we find it. The condition of the suffering of the civilized women of the present generation, however grossly unnatural it has been cultivated, must needs have our most careful attention and require our wisest judgment, lest we fail to institute proper treatment for their relief. In the care of pregnant women much of great importance devolves upon the obstetrician, with regard to safely conducting the mother through the period of gestation, parturition, and the puerperium; the preservation of the life and healthful condition of the child; and his own reputation. The diseases of pregnancy unquestionably is a field only partially and imperfectly explored. When we take into consideration how much of accident might be avoided and how much real good done to this class of suffering women by proper care, it places us at a loss to account for the fact that ob-

stetricians have hitherto neglected their duties, by signally manifesting a want of endeavor to promote the advance of obstetric science, in a direction quite worthy of the profoundest investigation. It is a noteworthy fact that the conditions which beget the disorders of pregnancy are not thoroughly treated by any of the standard works upon obstetrics. We are so busy thinking, discussing, defending, inquiring, practicing and teaching about the better modes of alleviating human suffering that we have no time and no leisure of mind for quiet contemplation, to allow the exercise of the intellect to feed upon Nature's truth, without which it is impossible to obtain a clear knowledge of the real causes and how to successfully prevent them. Communion with Nature was never more needful than now. Feverish activity rules all spheres of life. Medical effort is multiplied and systematized beyond all precedent. And all these things make calm fellowship with Nature hard to compass. We can conquer Nature only by obeying her laws, and in order to obey those laws we must first learn what they are.

For the convenience of our consideration, the paramount duties of the obstetrician in the study and care of pregnant women may be classified as follows:

1. To discover if the patient be actually pregnant.

2. To determine positively if the impregnation be uterine or normal, as contradistinguished from tubal, abdominal, or abnormal pregnancy.

3. To carefully note the pregnant woman's history, including her age, primiparity or multiparity, environments, station in life, general condition of health, period of gestation; as well as her dress, food, drink, and habits of life. To make repeated examinations of the urine and ascertain the temperature, from the time pregnancy is established to the termination of gestation.

4. To make a physical examination for the purpose of accurately determining the diameters of the pelvic straits; the symmetry and size of the bony outlet; the integrity, condition, and position of the vagina, uterus, and other inter-pelvic viscera and adjacent structures; the state of the abdominal muscles; the presence or absence of hernia, varicose veins, tumors, etc.; the shape, size and condition of the breasts and nipples; the condition of the heart, lungs, mind, stomach, bowels, etc.

5. To observe the state of the fetus, its strength and viability, as well as the implantation of the placenta.

These must all be included in the search for intelligent guidance as to how the proper management of the pregnant woman should be conducted. With regard to the first, all experienced observers have found that psychologic phenomena often call for an intimate study and wise differentiation of every form of hallucination, delusion, illusion, as well as the deilrium of cerebral hyperemia, or the frenzy of the maniac, from toxemia and eccentric irritabilities. And, that such abnormal conditions frequently exist unrecognized, and so continue until they eventually establish their peculiar fixed impress upon the mind and nervous system. Thus when the paranoiac woman simulated pregnancy, and even parturition, she deceived the better judgment of some of the most skilled obstetricians. Pseudocyesis and pseudotocia are recognized abnormal conditions, which so closely resemble the normal condition of pregnancy, and the beginning of parturition, as to demand our highest discriminative faculties in arriving at an intelligently correct diagnosis.

As to the second, it remains a simple self-evident fact that it should always be positively determined whether the impregnation be uterine or extra-uterine. How to intelligently differentiate normal or uterine from abdominal pregnancy, time forbids to discuss fully in this connection; suffice to say that it may be made by careful palpation of the abdominal parieties, together with vaginal and rectal digital examination and proper posturing. Paracyesis and interstitial or cornuate fetation are purposely omitted, as such accidents can scarce be diagnosed at a sufficiently early period of gestation to be of actual benefit. Abnormal implantation of the fetus constitutes a most important class of cases with which the accoucheur has to contend. Extra uterine or tubal pregnancy is rarely suspected until after certain dangerous and distinct symptoms are manifested, chiefly because no opportunity is had to discover it. These symptoms are such as follow rupture of the cyst containing the embryo with intra-

pelvic, or interperitoneal hemorrhage and shock; as sudden seizure of violent agonizing pain in the lower abdomen, fainting, pale, or anemic surface of the body, cold clammy skin, rapid and almost imperceptible pulse, sighing respiration, etc. Whenever extra-uterine fetation is discovered, either before or after the rupture of the cyst, the question of treatment is a very grave one. But experience teaches us that this truly marvelous and murderous condition admits of only one line of action to be followed with any degree of ultimate safety to the life of the pregnant woman. Section must be done. No other line of treatment that has been advanced is so rational and certain in the ultimate saving of life as abdominal section. The perfected technique, as we have it today, makes it a safe procedure. We must, however, bear well in mind what experience also teaches us, namely: that when the placenta is found still in the tubal sac it is best to enucleate and remove all—the tubal sac and ovary; but that whenever the placenta is found partially or wholly out of the tubal sac and adherent to the peritoneum, bowel, etc., and still alive, the very best that can be done is to let it alone—to keep hands off. In these cases the ultimate safety of the patient lies in removal of the fetus, cleaning out the peritoneum of blood clots and all other *débris*, ligating the bleeding vessels, pack with iodoform gauze, and treat as an open wound; thus allowing the placenta to come away in due course of time by suppuration. We can thus guard against sepsis by drainage and cleanse out the cavity as fast as putrescence develops. My most venerable friend and classmate at the University of Pennsylvania, Dr. Joseph Price, than whose experience in these cases there is none more extended and successful, and consequently deserves to be accepted as reliable authority, says: "All other lines of treatment that have been advocated fall into insignificance with this manner of managing these cases." He also claims this is a summer disease or accident, being in his experience almost always found only during the summer months; when May comes he looks for extra-uterine pregnancy cases.

The third brings us thoughtfully to consider the influences of those conditions which have been hitherto so grossly neglected, but which demand a decided and determined prophylaxis. The unprecedentedly rapid progress of civilization in disobedience to the law of Nature, as evidenced by the accumulation of wealth on one hand and extreme poverty on the other; the forcing or cramming system of intellectual education with lack of requisite physical training; the custom of unwholesome food and drink; deteriorating fashions of dress and habits of society; unbridled sensual indulgences; and the woful endeavor to equalize the duties of women with those of men, have within the last generation very much deteriorated the child-bearing capacity of civilized women. True, the standard of female beauty is increasing, and decided intellectual growth manifested by women in all departments of science and art; but, in the same ratio do we find the remote dangers as well as the immediate accidents of gestation and child-birth have increased. Hence, we find that flaccidity of the abdominal, spinal and pelvic supports; chronicity of the shattered exotic nervous systems; abnormal state of the ovaries; subinvolution of the uterus, etc., have marvelously increased in later years, notwithstanding the much-vaunted so-called hygienic advances in improved habits of living and reform in dress. These unnatural conditions are most prevalent among the residents of our cities, and increase from bad to worse as we go from the smaller to the larger and more crowded marts in civilization. They are as prolific sources of chloro-anemias, trophic-nerve paresis, hydremias, hyperemias, and prostrations during pregnancy among the women of wealth, ultra-refinement and excessive culture, as are those women who are subjected to the privations and hardships of extreme poverty. The remarkable fact in history being that there has been a proportionate increase of these conditions among the women of these two extremes of life, whereas the reverse holds good with women who belong to a middle class and are comparatively free from the unnatural behests of modern civilized society, or of irremediable poverty. The pregnant woman whose parentage, as well as herself, has been untrammeled with the deleterious impress of either of these two extremes in life, will terminate her gestation and parturition with much less suffering, and more healthful to herself and her offspring, than will her more unfortu-

nate sister who comes from a stock reared in the excesses of indolence, luxury or poverty. The pregnancies of too early, as well as of too late, marriages are alike to be apprehended as fraught with unnatural conditions. The girl who enters the matrimonial state at the nubile period, from 18 to 20 years of age, will approach the marriage couch with a much better prospect of wholesome fruition, healthy to herself and offspring, than will she who enters the nuptial relationship earlier, under the turbulence of puberty, immature physical development, and illy formulated morale, amid the storm-waves of exalted nerve tensions superinduced by over-taxed educational training, and undue stress of unwholesome fashion and society; or, than she who marries late, say after 28 years of age, who still retains all the productive elements but which have been debilitated by repeated disappointments, now leave her with the elasticity and resiliency of youth—the regulating factors in all growths—defective, and the newly stimulated energies of a life somewhat wasted are revived in a physical organism unfitted for the reproductive process. The ovaries and uterus may properly perform their respective normal functions from puberty to the menopause, but it must be remembered that an opportune impregnation is requisite to preserve woman, if not rosy and plump, at least elastic and buoyant; that her maternity may be exempt from pelvic indolence, so typically manifested by the flattened chest, the wrinkled face, and some fixed cultivated hobby—to save the rosy-cheeked maiden of 20 from shriveling into the parchment-skinned spinster of 40, by timely desuetude of celibacy. The primaparity or multiparity of the patient also demands its quota of consideration in the etiology of the diseases of pregnancy. The influences of heritage, personal habits, station in life and environments, usually make up the requisite field for the consideration in the primapara; whereas, in the multipara we find it essential to also look well after such conditions as the subinvolution of the uterus, lacerations of the cervix or perineum, tumors, and defective pelvic, abdominal and spinal support, as they often lead to abortion or to direct dangers during parturition.

The thoughtful obstetrician will, with inexorable discipline, advise his patient as to the requisite *régime*. The consciousness of his full duty will impel him to insist upon:

1. Absolute, regular hours and wholesome environment.

2. Plain but nutritious and wholesome food and drink, being principally composed of fresh lean meats, fresh fruits, pure milk, and distilled water.

3. A proper amount of exercise, by walking or light labor on foot and maintaining the correct erect posture. Whenever infirmity forbids such exercise, recourse should be had to massage, and as much time passed in the open air as is advisable under such unfortunate circumstances. Rest in the recumbent posture after meals and fatiguing efforts, with not less than ten hours sleep out of every twenty-four.

4. An open condition of the bowels and skin, which is to be chiefly maintained by proper diet, exercise and bathing, the wearing of flannels, warm low-heeled shoes and loose garments, and, in rare cases, the proper use of laxatives, and hot-water enemas.

It, however, not infrequently falls to our lot to have placed under our care pregnant women who belong to the poorer and less favored class, exposed to too much labor, privation of proper food, dress, and shelter; with whom we find ourselves confronted with the question for bettering their diet, dress and habitation, which assumes such proportions that demand our assistance, not only as medical men, but also as philanthropists. Fortunately the advantages which the many charities afford enable us to give this class much benefit in every way, save when mental anguish and nostalgia become irremediable factors, in the production of depressing influences which bar the healthful action of the resources at our command. With regard to repeated examinations of the urine and noting the temperature, it suffices to say that as are the urine and temperature so are, very largely, the prognosis and treatment prior to parturition. Urinalysis and thermometry are simple in detail, yet how prolific of averting the culmination of conditions very hazardous to both mother and child. Conditions which otherwise are frequently discovered only by the appearance of anasarca of the inferior extremities, edema of the face or lungs, or a seizure of eclampsia, after which attention

is given to these searching steps, but often too late to be of any value in devising a prophylaxis. This very naturally raises the question, Is there a prophylaxis for the albuminuria of parenchymatous nephritis during pregnancy and consequently the avoidance of eclampsia prior to or during parturition? The experience of an earnest rational endeavor in a limited number of cases warrants the opinion that very much may be done in this direction. So, also, with regard to the prophylaxis of parturial sepsis, which is a problem of equally great magnitude. True, sporadic cases of so-called puerperal fever (parturial sepsis) as well as of eclampsia, etc., ensue in spite of all possible efforts, but it is the writer's firm conviction that these murderous complications can and will be prevented by timely precaution and by banishing every factor in their production. Preparatory hygienic regulations, antisepsis and quarantining will as surely save the mothers from these complications as absolute cleanliness at parturition will save the child from ophthalmia neonatorum.

In proof of this, it is needless to confine reference to personal experience in private practice, for in addition we find the maternities likewise furnish abundant evidence in support of this declaration. Here we may cite, as the most striking example, the indefatigable labors of our eminent Fellow Dr. Joseph Price, in his connection with the Preston Retreat at Philadelphia, whereby both that institution and himself have become renowned, in establishing this fact beyond all doubt or cavil, that these complications can be prevented.

A word with regard to the term puerperal fever, which is misleading and fails to express the condition it is intended to imply. It should therefore be expunged from our literature and be replaced by the proper term, *parturial sepsis*. Parturial sepsis is a surgical sepsis, arising from the conditions in which women are found during the extrusion of the uterine contents, similar to those during surgical procedures. The same classes of septic infection and septic poisoning occur in the non-pregnant state, during operations upon the pelvic viscera done without due regard to absolute cleanliness, and in hospitals where patients are crowded together with want of proper sanitation. Facts, as numerous as can be collected in any department of medicine, prove conclusively that the infection and contagion of sepsis, non-specific and variable as they are, can be conveyed by the nurse or attendant as well as by the accoucheur, and thus may likewise poison patient after patient until they also, as well as the accoucheur, either discontinue their labors or subject themselves to the most rigid discipline of absolute cleanliness and sanitary environment. When this prophylaxis obtains, then will parturial blood poisoning cease to be among the cases intrusted to their care, and they will find themselves rewarded with a mortality of *nil* from sepsis. It is very clear to the writer that the more carefully we study and practice obstetrics on sound surgical principles, the better success will we obtain. This, above all else, will secure a thorough preparation of the vagina, that the child may make its exit into the world through a clean channel, which will insure safety to both mother and child. And again, if the forceps or the hand should be required, if laceration of the cervix or perineum should occur, the patient will then have the healthful benefit of the same preparation as is given for surgical procedure. A word also with regard to finding ourselves summoned during the latter period of pregnancy, or at the approach of parturition, to attend one who is suffering from or threatened with eclampsia, and the patient suffering chiefly from vascular excitement, I should feel it as much my duty to bleed, as I should to clean out the endometrium whenever parturial sepsis was found to be due to the retention of infected decomposing portions of the secundines. While, if the patient under like condition belonged to the more rare class of anemic cases, I should hope to happily correct the disorder by chloroformation, hot water, the hypodermatic use of morphin and atropin, veratrum viride, etc.

Under the fourth head of the subdivision of this subject, it may be remarked that pelvimetry is an equally essential requisite with urinalysis and thermometry. Deviations from the normal symmetrical pelvis, the diameters of the pelvic straits and the inclination of the bony excavation, exercise marked influences in proportion to the degree that they exist. In an abnormally broad capacious pelvis, with obliquity lessened and supports relaxed, we find that in the earlier period of gestation

the tendency is to misplacement of the gravid uterus, either forward or backward and downward, from gravitation in consequence of increased weight. These abnormal uterine positions are usually manifested early by bladder or rectal difficulties with bearing down or pressure in the pelvis, and a dragging sensation from the lumbo-sacral region, etc. The functions of the intra-pelvic nerves, blood vessels and lymphatics being interfered with, we find in a proportionate degree that there is produced a stasis in the venous, vaginal, uterine and rectal plexuses, and consequent dilation of both these vessels and the lymphatics. Thus we have produced a hyperemic state of the entire pelvic circulation resulting in edema primarily, followed by ecchymosa of the peri-vascular, peri-lymphatic, and other cellular tissues, to be succeeded later by varix of the vulval, vaginal, uterine and hemorrhoidal venus plexuses, and consequent trophic nerve changes. It is a noteworthy fact that in these cases there is almost invariably found a want of the correct erect posture. The woman, herself, unconsciously increases the aforesaid difficulties by assuming a more or less stooping posture, in her endeavor to make herself comfortable from the dragging sensation below. Thus we find the abdominal and spinal muscles relaxed, the lumbo-sacral spine receding behind its normal axis-perpendicular with ear, shoulder, hip and ankle—the weight of the superior trunk gravitation back of this normal axis and falling perpendicularly behind the heads of the femurs; whereby the pelvis is swung upon the femur heads from an oblique to a more or less transverse position, while the superincumbent weight of the abdominal and thoracic viscera, instead of being directed forward, by the normally advancing lumbo-sacral spine and supported upon the pubes and lower portion of the abdominal muscles, now falls directly within the basin of the pelvis, exerting its injurious effects upon the contents thereof. The real causes of these conditions being thus clearly revealed, the treatment becomes very simple. This consists in first reëstablishing and maintaining the correct erect posture, thereby securing the normal obliquity of the pelvis by advancing the lumbo-sacral spine in its normal axis of the body. The superincumbent weight of the abdominal and thoracic viscera is then again directed to normally gravitate upon the pubes and lower border of the abdominal muscles, and at the same time there is afforded the normal shelter to the pelvic contents below and behind the promontory of the sacrum. Experience has established the fact that the correct erect posture in these cases is secured and maintained the more effectually by virtue of proper external support. The external support which fulfills this purpose the better is one fully detailed by the writer in a paper read before the International Congress of Gynecology and Obstetrics, at Brussels, Belgium, September, 1892. (This support is manufactured by the Natural-Body Brace Company, Salina, Kan.) The normal equipoise of the superior trunk upon the lumbo-sacral spinal axis having been thus restored, whereby the evil influences from the weight adove as a prime causative factor in intra-pelvic disturbances are happily overcome, there remains but attention to be given to the insignificant weight of the misplaced pregnant womb itself. This is usually easily corrected, when free from adhesions, by proper posturing, and afterward maintained by proper internal support with some pessary suitably fitted to the case.

When, on the other hand, the pelvis is abnormally distorted or contracted, the question of how best to conduct the gravidity has been even a more unending source of discussion than the preceding condition. Here pelvimetry furnishes us the chief guidance. But before we progress further, let us first break loose from the traditional shackles of our predecessors and their authority, which have so long retarded freedom of thought to such a degree that he who dared to doubt met but derision. I refer chiefly to the murderous practice of inducing premature delivery and embryulcia in this condition. In the present light of science these procedures have no place in the obstetric art in connection with a viable fetus. They simply deserve to be mentioned that they may be the more effectually relegated to the past. This leaves us to choose principally between but two procedures whenever we find the pelvis so distorted or contracted that it precludes all probability to deliver the living child, namely, symphyseotomy and Cæsarean section. Without specifically considering all the points of this very serious condition—which,

fortunately for us, is, comparatively speaking, very rarely encountered in the native-born American women—I would unhesitatingly advise against the termination of gestation, looking more hopefully to ultimately saving the life of both mother and child by resorting to one of the aforesaid operations. It is to be remembered, however, that it is the duty of every intelligent obstetrician to become thoroughly familiarized with the indications as well as the technique of both these operations, neither of which is to be lightly undertaken by any one who does not possess the requisite skill, both in the obstetric art and abdominal surgery.

With regard to the proper selection of these two operations, I can do no better than quote Dr. Barton Cooke Hirst, of Philadelphia, in his address before the Washington Obstetrical and Gynecological Society, November 17, 1893, and published in the *Medical News* December 2, 1893: "It is obvious, therefore, that symphyseotomy can be preferred to Cæsarean section on the one ground alone—that it is less dangerous to the mother. A careful study of the results of symphyseotomy and of Cæsarean section will show that the latter is, at the very least, twice as dangerous to the mother as the former. The mortality of the infants is not quite so great in deliveries by Cæsarean section. Moreover, by Cæsarean section the child is sure to be delivered easily, no matter what the size and shape of the pelvic canal may be, and there is no necessity for that nice calculation in pelvimetry that is usually demanded before a contemplated symphyseotomy, a calculation in which even the best of us may err. With my own experience of three perfectly uncomplicated recoveries from symphyseotomy, I feel disposed to regard this operation with more favor than version and extraction in a markedly contracted pelvis. The opposite error of opening the symphysis when the pelvis is too small to permit of delivery by this means is more difficult to escape. It will only occur in a pelvis with a conjugate of sixty-seven millimeters, or under, a degree of contraction not often seen among us; and could we always be sure of the accuracy of our pelvic measurements, the mistake would pretty surely be avoided. I can imagine no more embarrassing predicament in obstetrics than a failure to extract the head after opening the symphysis. I should feel reluctant to operate again at the lowest limit for symphyseotomy unless I had the opportunity first to induce labor and artificially dilate the cervix some two or three weeks before term. In this case I should not hesitate to operate with a conjugate as low as sixty-five millimeters, and I believe delivery might be possible with a conjugate of only sixty millimeters. We may therefore be guided by the rule that at term, symphyseotomy is available only in cases where the conjugate measures over sixty-seven millimeters, while if the conjugate is found to be sixty-seven millimeters or under, the only recourse to be had is Cæsarean section."

The destruction of the embryo is, however, not only warranted, but becomes a requisite under certain circumstances or conditions; such as the presence of large fibroids in the body of the uterus, or large tumors involving both the ovary and uterus, also cancers of the uterus, and in certain cases, of placenta previa. Placenta previa is another abnormal condition deserving attention. It properly belongs to that class of appalling accidents in the lying-in room, as eclampsia, post-partum hemorrhage, rupture of the womb in uterine pregnancy or of the cyst in tubal pregnancy, etc., which allow but little time for action. Experience teaches that the proper use of forceps in these cases is to be preferred to the hand. The chief reason being that a narrow-bladed forceps can be introduced much earlier than the hand—requiring a dilation of only about one inch as compared with two and three-quarter inches for the hand—and, by grasping the head and bringing it down, tampon the placenta at once; whence time may be given sufficient to obtain full dilation and delivery with greatest possible safety to both mother and child. In these cases we may very properly follow the one line of action. As soon as the diagnosis of placenta previa is established our action must be prompt in evacuating the uterine contents. Hemorrhage is the danger signal. When this signal is given early, say prior to the sixth month, and the diagnosis established, we should proceed without any regard for the life of the child. When, however, this signal is given later, we should proceed as promptly, but with all possible endeavor to save the life of both mother and child. Whenever hemorrhage

takes place in these cases it is Nature's signal to us that there is great danger ahead; that the condition is so serious as to endanger, if not to take, the life of the mother at any moment. We cannot accept the situation only as serious, and must act promptly and effectually. The proper antiseptic precautions being observed with special reference to the vagina and the accoucheur's hand, the patient being placed under anesthesia, introducing first the index finger into the cervix, dilating gradually until two fingers are successfully introduced, and, when sufficiently dilated to admit of the forceps, pass the fingers through the body of the placenta, rupturing the membranes and place the forceps on the head, bringing it down and tampon the placenta at once. When, as sometimes happens, the dilation is greater and the presentation abnormal or less favorable, the accoucheur had better resort to the passing of his hand and turning by Braxton-Hicks' method and drawing the child into the cervix, and thus arresting the hemorrhage. The hemorrhage once checked, the subsequent delivery will be fully under control.

I have in this paper but sketched some of the salient and mooted points of the prophylaxis of the complications and needless sufferings of pregnancy, with no attempt at thoroughly elucidating or elaborating any one of them. Having no pet theory to promulgate and sustain at all hazards, no long list of cases and statistics with quotation and abstract from an exhaustive roll of writers has been made out.

CHRISTIAN SCIENCE AGAIN.

E. M. CLARK, M. D., PHILADELPHIA, PA.

If "Christian Science," the theme of Dr. Longsdorf's paper read at the recent State Medical Society and published in THE MEDICAL AND SOCIETY REPORTER of August 11th, were not a misnomer, it would long since have found ardent advocates among two very pronounced classes of the community, viz: professing christians and men of science, especially of medical science.

The purpose of the writer, however, is not to discuss the theories and claims of this so-called science and its votaries, but rather to appeal to members of our own profession to make more practical use of the one very important truth which forms the warp and woof of all the flimsy sophisms of Christian Science.

Dr. F. C. Herr (MEDICAL AND SURGICAL REPORTER, September 8th) says, very pertinently, "I am quite sure that Dr. Longsdorf must have made a grave error when she says that, 'Christian Science must not be confounded with hypnotism, animal magnetism, faith or mind cure, spiritualism, clairvoyant or other trance or the old-time pow-wowing process.' If Christian Science is not these things, we have abundant reason for alarm, but it is the same old imposter in masquerade dress."

We well may relegate the thing itself to the domain of quackery, and assume towards those who claim to be healers under its provisions, the same attitude that the medical man always takes in the presence of pretension without foundation. He ignores and is indifferent.

Without any critical analysis of the basis upon which Christian Science, along with other allied subjects, rests, we cannot fail to see that the domination of mind over mind easily persuades to a belief in the domination of mind over matter. So far, the advocates of all such methods of healing are rational and scientific in their belief.

Certainly in these days of experimental physiological research, no well-read physician will dispute the fact that mind, or mentality—the volitional and automatic processes of cerebration—does to a great extent modify and control the ever varying conditions of the material man.

Foster (Physiology, Part III, Central Nervous System) says: "Consciousness, as we recognize it, seems to be necessarily operating as, or to be indissolubly asso-

ciated with the presence of, an incessantly repeated internal stimulus, and we cannot conceive of that failing to excite mechanisms of movement." If this be true, then given an influence to bear upon our patient sufficient to bring about that *incessantly repeated internal stimulus*, and what results may we not hope to accomplish.

It seems almost futile to mention illustrations along this line—they will readily recur to all. Pathological conditions most varied and remote are known to result from violent and sudden emotions of either fright or anger, grief or joy. Happiness is a fine cosmetic and is just as sure to promote health, as worriment and care are known to be prolific sources of that faulty metabolism which, sooner or later, results in disturbed function, and may result in almost any visceral lesion.

What are the various functional neuroses but the product of perverted nerve action? We repeat, mental states have produced diseased conditions almost innumerable, from the simplest vaso-motor disturbances familiar to all, as pallor and syncope, to even the more complex clinical picture of diabetic coma* from nervous shock. Dyspnœa, cough, emesis, the inhibition of reflex movements through a counter stimulus, menstruation influenced favorably or unfavorably, the salivary secretion induced or exaggerated by smell or sight of food, even pain ignored and therefore practically expelled by diverting the mind—these are but a few of the physical phenomena occurring in consequence of certain mental states. Apropos of this same truth is Professor Pontain's very interesting article on "Emotional Icterus," (MEDICAL AND SURGICAL REPORTER, September 15th), which, he asserts, "If primary, may be cured without drugs if the patient be in *a tranquil state of mind.*" If disease can be induced thus, it certainly behooves the physician to endeavor to find a way to reverse the process, that he may substitute harmony for discord and ease for disease.

Referring to the many undoubted cures wrought by these would-be scientists—Christian or otherwise, Dr. Longsdorf says truly, "To a rational thinker there is no mystery about the process," but we think she errs in assuming that "it can not be rationally explained so that the subject of it can clearly understand."

That is one of the strongholds of these occult methods—those who practice them trade upon the gullibility of the weak in body and mind. Whereas the regular physician may use not only all the resources of his medical art, but should also use all the powers of his trained mind to dominate the mind of his patient and teach him how to use his own will towards the betterment of his physical condition.

The successful practitioner knows that he owes his success to something more than his efficacious prescriptions; just how large a factor is his personality and the power he possesses to win the confidence of and to control his patient, he may not be able to determine, but he certainly is conscious of it.

Kant has said, "In our moral consciousness we find ourselves under a law which calls upon us to act as beings who are absolutely self-determined or free, and which therefore assures us that our intelligent self is our real self."

Let the wise physician demand that his patient *be* his intelligent self, and act accordingly. Let him seek to arouse the moral consciousness of his patient to a sense of his own inherent power. Let him endeavor at least to induce that tranquil state of mind which certainly assists not only nature but the doctor to work marvellous cures. It may not be quite so easy as to prescribe pills and potions, but this moral consciousness once aroused will become a mighty adjutant to the proper physiological action of whatever therapeutic measures may be instituted. It is like Aristotle's fulcrum, "A fixed point on which reason can set its lever as a secure basis from which to move the human will even against the opposition of all the powers of nature." The neurologist understands this truth and makes use of it. Why should not the general practitioner do the same in selected cases? Where the nervous element is a factor in initiating a diseased condition or in the continuance of it, there is a field and a large one for mental therapeutics.

TREATMENT OF ANAL FISTULA.*

J. McFADDEN GASTON, M. D., Atlanta, Ga.

PART I.

For a proper understanding of the principles underlying the management of anal fistula, it is requisite to present some data connected with the rectum.

Morton and Witherill state that the rectum in its upper and middle portion is derived from the internal and middle layers of the blastodermic membrane, while its lower third with the anus, like the buccal cavity, is formed by the external and middle layers. The rectal veins like the rectal arteries are divided into three sets: superior, middle and inferior. They form two distinct venous systems, the rectal emptying into the portal system, and the anal terminating in the internal iliac.

The throat and rectum have many points of correspondence in their structure, being supplied with circular fibers, which make them the counterparts of each other, by opening and closing their respective orifices. There are two sets of muscular fibers encircling the lower part of the rectum, known as the outer and inner sphincter, by which it is automatically closed except when dilated voluntarily for the release of flatus or the discharge of fecal matter. There is also another distribution of circular contractile muscular fibers at the upper limit of the rectum, which constitutes the division between it and the sigmoid flexure of the colon. This may be appropriately designated the recto-colic sphincter, and forms an effective barrier ordinarily to the descent of the excrement into the rectum. This annular muscle has not received from anatomists or physiologists the consideration which its rôle in the intestinal functions warrants. It is a veritable constriction from muscular contraction by which the colon is normally closed against the descent of the fecal mass into the rectum. When the excrementitious matter reaches the sigmoid flexure of the colon it is deprived of all the nutritious properties and after this desiccated mass passes the muscular division between the colon and rectum, and is deposited in the lower reservoir it contains only effete matters.

The fecal deposit acts then as a foreign body, and stimulates this canal to expel the débris by the anal orifice, or by remaining there becomes a source of trouble and even of disease. If the indurated mass remains in the rectum for an undue period, it induces more or less local disturbance and extends an etherism to the general system, through the nerve supply to this portion of the organism.

The rectum is a pouch or depository consisting of contractile tissue and capable of great distension under the accumulation of the fecal matter within it. While its proper function is that of a temporary reservoir with the property of contraction for the expulsion of its contents, it may fail to perform the office of a waste pipe and become shut off as it were by sphincters above and below. These annular muscles are provided with somewhat similar means of opening and closing at each extremity of the rectal canal; and being composed of tissues in their walls, which are alike subject to induration and thickening, with constriction of the passage.

Zeigler qualifies proctitis as an inflammation of the rectum, resembling in many points inflammation of the vermiform appendix. The exciting agents are frequently foreign matters and stagnating feces; but disturbance of the circulation in the hemorrhoidal veins may likewise end by inducing inflammatory change in the bowel.

When the inflammation and ulceration extend deeply into the tissues of the wall of the bowel, the surrounding connective tissue becomes infiltrated and hypoplastic or breaks down into abscesses containing fetid pus.

Thus it occurs that the rectum becomes a seat of disease and among its disorders fistulæ are not uncommon, either as sequelæ of peri-rectal abscesses or resulting from abrasions and ulceration of the inner coat.

*Read by title before the Section on Surgery, American Medical Association, 1894.

Apart from fecal concretions and enteroliths lodged in the rectum and becoming sources of irritation and inflammation to its mucous coat, there are foreign bodies which pass through the alimentary canal and find their way into the rectum to cause trouble in the surrounding structures. Fish bones, spiculæ of chicken bones and other bony fragments have frequently been found in peri-rectal abscesses after having perforated the rectal wall. Very recently I removed a spicula of bone over an inch in length which had become lodged just within the external sphincter, and one extremity had perforated into the mucous membrane of the rectum. This would have ultimately effected an opening through which the fecal matter could have penetrated the tissues and set up a suppurative process. The incautious introduction of a syringe pipe or other solid substances may also induce abrasions of the mucous membrane of the rectum which will terminate in ulceration and perforation of the rectal wall.

The attempt to remove hardened fecal matter with a scoop or with the fingers may lead to a bad result. But there are scores of disorders from injuries inflicted in the parts immediately around the anus, which set up inflammation of the deeper seated structure. Violence of any kind, by a kick, sitting down upon a projection, or being thrown upon the pommel of a saddle, may lead to a peri-rectal abscess, which calls for considerable skill in its treatment to avert its termination in a fistulous outlet. The early recognition of such a purulent collection and its discharge by a free incision, with the subsequent use of a drainage tube and light tamponage with antiseptic gauze, is usually attended with a radical cure of such traumatic abscesses. But there will occur cases which will resist treatment or which fail to be properly managed, that result in fistula.

There is a class of tuberculous abscesses in the peri-rectal tissues which are of strumous origin, and independent of any mechanical injury, that are accompanied by fistula of the most aggravated type. This form calls for constitutional as well as local treatment.

It is not a legitimate inference that the drain of a fistula upon the adjacent rectal structures has a salutary influence upon tubercular diseases of the lungs. The evidence is conclusive to my mind that the general debility and constitutional irritability, resulting from the constant wear and tear of fistulæ involving the tissues around the anus, are in most cases aggravating circumstances in the progress of other diseases, and the more effectually they can be cured the better the result. There was a period when the names of distinguished members of the medical profession were arrayed against operating for fistula in ano when it occurred in a tubercular subject. But the weight of authority is now favorable to operative interference for eliminating the local disorder and arresting the drain upon the system.

Instead of the chronic cure by a slow treatment for fistula in ano, with oft-repeated temporizing applications, in subjects of tubercular disease, it is decidedly preferable to secure the prompt effect of a speedy and radical operation in cutting short the evil.

The openings may occur at distances from the anus, varying greatly, both internally and externally. Where there is a sulcus forming a semi-circle around the lower portion of the rectum, it is recognized as a horseshoe fistula, and may have the opening in the skin on the opposite side from that in the wall of the bowel.

The usual division of complete and incomplete is based upon the existence of an external and internal opening in the former, and either one or the other in the latter. Those having but one opening are known as blind fistulas and we may have a blind external or a blind internal fistula, as the opening occurs in the skin outside of the anus, or in the mucous coat within the anus.

The cases in which the two openings in close proximity to the anus are presented, usually involve only the external sphincter, and have the internal orifice between this and the internal sphincter in the depression which exists in the space between the two muscles. This is accounted for by Allingham in the following manner: "The abscess forming, in most cases just outside of the anus, does not burrow deeply but passes close under the external sphincter; it then is prevented from ascending higher up the bowel by the thick band of the internal sphincter, and consequently is turned inward and makes its way through the lax areolar tissue." This explains those cases in which the primary

abscess is outside of the rectum; but a large proportion of fistulas have their origin inside, and by perforation of the rectal wall admit the fecal matter which works its way by suppuration out through the skin beyond the border of the anus, forming a complete fistula.

When the abscess commences in the ischio-rectal fossa it burrows deeply, according to Allingham, and then most usually passes beneath the internal sphincter and opens, if at all, high up in the rectum. There may be more than one aperture in the rectal wall communicating with the different fistulous tracts, leading out through the skin at varying distances from the anus. When the openings occur high up in the wall of the rectum, and the suppurating process extends from these into the surrounding tissue of the buttock, several external orifices may be found in the skin of the hip, even at a distance of six or eight inches from the anus. Comparatively few of these cases have been noted in this country, but quite a number of them came under my observation during my sojourn in South America. Some of these extensive fistulas will be referred to in connection with the surgical measures adopted for their relief.

The foregoing pathologic indications have not included a distinct recognition of what constitutes a fistula, and it may be defined as the ulcerated outlet of a suppurating tract through the subcutaneous tissues. This irregular and often tortuous channel is surrounded by a pyogenic membrane, bounded by a fibrinous deposit, which imparts a sense of induration to the touch by palpation. The object of treatment in any form should be the obliteration of this canal and the apertures connected with it, whether internal or external.

PART II.

As a preliminary step toward any measure of treatment for fistula in ano, whatever may be its form, it would be desirable to have the bowels frequently evacuated for two successive days, and to use an enema of warm soap water during the morning of the day fixed for an operation. After this procedure the patient should be placed upon the side, with the hips projecting over the edge of the bed so that the fistulous opening shall be uppermost, and a speculum introduced into the rectum with a view to open moderately the anus. A syringe with a small beak may now be employed to pass a 50 per cent. solution of the peroxid of hydrogen from the external aperture through the fistulous canal and out at the inner aperture, leaving it to escape through the dilated anus. This should be followed with an injection into the fistula of a mixture of one drachm of the concentrated Lugol's solution with four ounces of warm water, letting it escape by the anus, as in using the other wash. Lastly a stream of sterilized warm water should be passed through the fistulous tract and the patient is ready for whatever operation may be indicated.

Various processes have been employed for the cure of anal fistulæ, some of which look to the correction of the conditions involving the use of injections into the tract, while others by mechanical devices procure its obliteration, and again the more radical measure of a cutting operation is held to be the most effective treatment. It is evident that different modes of procedure are requisite, according to the nature of the case, and that which is applicable to the superficial complete anal fistula cannot be adopted in the deep-seated anal fistula with one or more apertures in the bowel communicating by fistulous tracts with several outlets in the skin at varying distances from the anus.

When there is an external orifice within an inch or less of the margin of the anus, and an internal opening within an inch or less of the aperture of the anus, the knife may be safely employed. A grooved director being introduced at the external opening is carried gently along the tract of the fistula until it emerges from the internal opening into the lumen of the bowel, when the index finger of the left hand is passed into the anus and up to the end of the director.

If from any cause the director is not found protruding, it should be guided by the finger into the aperture, or if not found, the end of the director may be forced through the thinnest part of the intestinal wall; and then passing the end of the finger beyond the point of the director it should be brought outside. The tissues lying between the external and internal openings of the fistule are now resting over the director and entirely exposed to the view of the operator. At this point

I have found a departure from the custom of using a curved bistoury to give satisfactory results, and would advise the broad straight bistoury to be placed with its back in the groove of the director and thrust through this intervening structure, which includes the external sphincter muscle. If the fistulous tract is not located at the right angle to the border of the sphincter, the director should be forced into a position to make the cut transverse to the fibers of the sphincter muscle.

The next step is scraping out or curetting thoroughly the fistulous tract so as to remove the pyogenic membrane, and thus place the bottom of the wound in a favorable condition for the process of granulation. Packing the line of the fistula from the external to the internal opening with iodoform gauze, and filling up the incision with loose gauze over this, a compress may be secured with a T-bandage to keep the dressing in position.

There is usually so much sero-sanguinolent oozing after this operation as to soak the dressing and require redressing within twenty-four hours. When fresh dressing with iodoform gauze is thus applied, no further change is requisite for three days. Unless a movement of the bowels should take place there can be no object in removing the dressing, but if a fecal evacuation occurs, the parts should be thoroughly washed with carbolized water from a syringe, and the dressing re-applied as previously. So soon as the bottom of the incision along the fistulous tract is found to be studded with granulations, the packings should be discontinued and the sides of the wound brought in contact to secure union of granulation in all parts.

The practice of former times, in keeping the sides of the incision separated by lint or gauze until the wound fills up with granulations from the bottom, is a fruitful source of protracted suffering to the patient and conducive to that loathsome result of inability to retain the feces and intestinal gases. If the curetting is done efficiently at the outset and the packing applied properly in the bottom of the wound for one week, the granulating process ought to be so developed in this time as to warrant the closure of the incision. By the use of firm compresses on either side, held in place by strips of adhesive plaster or bandages, an operation of this kind should not require the attention of the surgeon more than two weeks. The union secured in this way between the divided parts of the sphincter obviates all inconvenience afterwards from fecal incontinence.

The attempt to dissect out the tract, when a fistula is laid open, has not been attended with results which encourage the immediate closure of the incision after an operation and hence need not be dwelt upon here.

In regard to those cases in which the internal opening of the fistula is found above the internal sphincter, but within two inches of the anal orifice, while the external opening is something over an inch from the margin of the anus, the knife may still be employed with safety. But in view of the difficulty or even impracticability of turning the point of a grooved director out at the anus, the process may be modified by introducing a concavo-convex wooden guard into the rectum to receive and support the point of the director when it emerges from the internal opening of the fistula.

An assistant should hold the director firmly while the operator secures the guard and makes the incision with the broad straight bistoury, by thrusting it along the groove of the director until the guard is is reached and then cutting inward so as to divide all the intervening tissues. The subsequent management of the case corresponds very much to that above described, except that the packing must be carried higher up into the rectum to reach the end of the incision.

In this class of cases the elastic ligature has been employed with satisfactory results by some operators. It certainly has at least the recommendation of lessening the liability to hemorrhage which attends a cutting operation that extends above the internal sphincter. There is a decided advantage in using the elastic ligature instead of silk or other material which only cuts through a limited portion of the inclosed tisssue, as the latter must be tightened from time to time, whereas the former continues the constriction until all the tissue is divided. In either case, however, there must be considerable delay in the process of cutting through the structures involved, and there is suppuration continuously, not only along the original fistulous tract, but from the entire surface

left behind the ligature as it cuts its way out. Under these unfavorable conditions it is very desirable to adopt another procedure which may accomplish the end in view more expeditiously, without hemorrhage and without suppuration. All these requirements are fullfilled completely by employing the chain ecraseur. This is suited not alone to the fistulæ having an external and an internal opening within an inch to two inches from the anus, but to those opening high up in the rectum and at a distance of several inches outside of the anus, through one or a number of apertures in the skin of the buttock. Having treated some cases of deep-seated extensive fistula in ano by this process during my sojourn in South America, which were reported in the *American Journal of Medical Sciences*, of July, 1881, I will present a few of the points recorded in that paper, to which members are referred:

If the source of the fistula is high up in the rectum, the route of the discharge may be in the direction of the sacrum or through the muscular fibers of the gluteus, and there may be several lines of communication with the surface. When the tract penetrates to such a depth as to cause apprehension of hemorrhage by cutting with a knife, the tissues may be divided without any risk by the chain of the ecraseur of Chassaignac. The essential conditions which indicated this operation have been observed in four cases of extensive fistula in ano.

The internal opening in each case was high up in the rectum, and the fistula extended from this aperture deeply into the surrounding tissues, so that the line of communication between the internal orifice and the external outlet of these fistulæ exceeded six inches in length, involving the structures on a large scale.

As the space allowed for this paper does not admit of details and the record of the treatment with two chains at the same time is given in the report of the last case, it may be quoted verbatim from the journal. Chloroform anesthesia was used in all cases: "Case 4, had two deep fistulas, whose external outlets were nearly equal—distant from the junction of the sacrum and coccyx on either side, having each a communication with an opening about midway up the rectum. The channels being tortuous could not be traversed by a metallic probe or director, yet they were explored by a flexible bougie, to which the chain of the ecraseur was attached, and thus loops were thrown around the intervening parts. Two instruments were used so as to encircle the tissues on either side and divide them at the same time. As the chains included a portion of the buttock containing no vessels that could yield any amount of blood, the tightening was done rather too fast, and as a consequence there was some sanguineous oozing from the divided surfaces of the muscles. This, however, ceased upon the application of a strong aqueous solution of phenic acid, which has proved in my hands an effective hemostatic, even when small arterial twigs are divided by the knife.

"The usual dressing of fine strips of old linen saturated with carbolized oil was kept up for some weeks, and the cure was completed within two months, so that the negress went about her duties on the farm."

The most remarkable feature in connection with these extensive divisions of the deep-seated fistulas, involving the cellular tissue with the muscular fibers surrounding the rectum, is the comparatively slight effect produced upon the general system. There has been little febrile excitements and the restorative process has progressed satisfactorily after all these heroic operations.

Borax as an Aid to the Digestion of Milk.

Germaine Sée has recently announced the clinical fact that borax used internally is a valuable aid to the digestion of milk. He discards the use of carminatives, charcoal and other intestinal antiseptics, claiming that they injure the mucous membrane of the intestines. He employs laxatives—hydrastis canadensis, castor oil, and olive oil in large doses, or oil enemeta. Prof. Sée holds that in many cases of indigestion the stomach is erroneously treated when the real cause of the disease is the intestines, which are often the seat of membranous enteritis resulting from constipation, and giving rise to glary, mucilaginous, cylindrical masses of mucus, with pain and swelling over the region of the colon. These symptoms easily distinguished the cases referred to from ordinary constipation, in which there may be easily seen masses of filamentous or vermicelli-like mucus.—*Modern Medicine.*

LUBRICATING CATHETERS.

L. D. MORSE, M. D., San Mateo, Cal.

In the number of the Medical and Surgical Reporter for May 19th, Dr. J. M. Kitchen is quoted as recommending castor oil as an excellent material for lubricating catheters. I have seen, at different times, the same recommendation by other physicians.

I differ most seriously from this opinion. I do not believe that castor oil is non-irritating. If so, why does it act as a cathartic? I have seen a good deal of of irritation caused by using it to clean foul sheath in horses. It is excellent to oil buggy axles. It has an unpleasant odor. It is tenacious truly, and according to Dr. Kitchen, "should always be applied warm." Who, that is obliged to use a catheter three or four times a day, often away from home, would like to be bothered with warming nasty castor oil every time he had to urinate? And wherefore? It is absurd.

I am in the middle of my 73d year. For the past four years, in consequence of an enlarged prostate gland, I have had to use a catheter, and cannot urinate without it.

I use exclusively the soft, rubber catheter. For a lubricant I use California olive oil—*pure*. I am safe in saying that all imported olive oil is adulterated with cotton seed oil to the extent of at least two-thirds. This has been proven. In California we have a law that forbids any one, under penalty, from selling under the name of California olive oil, anything but the pure article. One concern, at least, has been forced to change their label to "salad oil."

To an ounce of olive oil I add twenty to twenty-five drops of eucalyptus oil, as an antiseptic. The catheter, after using, is rinsed out in Zymocide or Listerine, and is most of the time left in a bottle containing one or the other of these antiseptics. The utmost cleanliness as well as antisepsis, is required to prevent a urinary odor which will lead to inflammation. I have learned by bitter experience what I probably would not have learned otherwise.

I may add that I have found pure olive oil very useful for partial or general inunction, more especially in the eruptive fevers, and, I think, is much preferable to any seed oil. It may be medicated according to circumstances. I often use eucalyptus oil, and sometimes carbolic acid in the desquamation of scarlatina.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

A CASE OF SEVERE DIABETES CURED BY OPIUM IN LARGE DOSES.

Dr. K. Bohland (*La Semaine Médicale* No. 48, 1894) reports the case of a man of fifty-nine years, of alcoholic parents who, very weak and emaciated in spite of an antidiabetic diet, passed during twenty-four hours three to four litres of urine, containing 100-200 grams of sugar, but without trace of albumen, acetone or diacetic acid. His appetite was decreased and his skin dry; the internal organs were apparently normal. Antipyrine and other antidiabetic remedies were of no avail; a sojourn at Neuenahr only caused an aggravation. He then began to suffer from insomnia and bilateral sciatica, while his emaciation increased still more. Bohland then prescribed him laudanum (Sydenham's), fifteen drops, three times a day. As the pains were intense, the patient rapidly increased the dose to two to three hundred drops a day; at the same he maintained a strict antidiabetic diet. Under the influence of this treatment the sugar commenced to diminish, little by little, so that at the end of a few months, it had completely disappeared. At this

* In charge of the Translator, F. H. Pritchard, A. M., M. D.

period he presented the characteristic signs of chronic morphine poisoning; his pupils were contracted, he complained of trembling, weakness of memory and considerable general debility. Nevertheless he continued to take the drug, in teaspoonful doses. The urine was passed in normal quantity and contained neither albumen nor sugar, though he partook of a mixed diet in abundance. The glycosuria did not then return even when he took one hundred grams of sugar, in his food. Externally, there was nothing abnormal to be seen; no signs of arterio-sclerosis. The patient was gradually weaned from the drug and, at present, he enjoys good health and is able to work. He has gained forty-two kilograms in weight; his appetite is excellent and his urine never contains the least trace of sugar, but he has developed a cataract in each eye.

TREATMENT OF DIPHTHERIA.

Dr. Brasch (*Muenchener Med. Wochenschrift* No. 18, 1894) has employed, at various times, different methods in the treatment of diphtheria. Since 1889 he uses the following measures. In patients over twelve years of age, where they are able to gargle every hour or two, they are allowed to use with the following:

℞

Corrosive Sublimate	0	1	(grs. jss)
Chlorate Soda	2	0	(grs xxx)
Distilled Water	200-300	0	(℥vjss-ixss)

Antipyrine or the salicylate of soda may be given for the fever, the latter with addition of pilocarpine (0.001-0.005) once to twice a day, as the membranes dissolve more or less rapidly. In grave cases and in small children, he recommends the cyanide of mercury, internally, from the very beginning of the disease and in the following form:

℞

Cyanide mercury	0	1	(grs. jss)
Distilled water	250	0	(℥viij)
Simple syrup	50	0	(℥jss)
Tr. Aconite	1.0-2	0	(gtts. xv-xxx)

A small teaspoonful every half-hour, hour or two hours, in a glass or an earthenware cup, but not from a metallic spoon, according to the severity of the case. For a quarter of an hour after its administration neither food nor drink should be given. Give the remedy day and night.

TO DISGUISE THE URINOUS ODOR IN INCONTINENCE OF URINE.

Dr. Brassert (*La Semaine Médicale*, No. 48, 1894) has taked advantage of the fact that patients under the influence of essence of turpentine excrete a urine smelling strongly of violets, in treating cases of incontinence, etc., where an insupportable odor is given off by such patients. Ten drops of rectified essence of turpentine three times a day, suffice to cause the nauseating odor to disappear and to be replaced by an odor of violets, to the great satisfaction of those about the patient. It may be administered in a little water or milk. It has been used for a long time at Prof. Emminghaus's psychiatrical clinic in Freiburg. It may be continued for several weeks without inconvenience, and is only contra-indicated in ulcer of the stomach, gastric catarrh, nephritis or where it causes dyspepsia or other morbid disturbances. This is a precious measure in private practice where it is difficult to keep such a patient clean from lack of proper care. Another deodorizer which is also used at this same institution, especially in those patients whose cutaneous secretions are fetid, is to give a daily bath to which has been added three or four grams. of permanganate of potash. This has no injurious effect upon the general health of the patient, and rapidly causes the disagreeable odor to disappear.

HYOSCIN IN HYSTERO-EPILEPSY

Dr. Bela Nagy (*Pester Med.-Chirurgische Presse*, No. 8-9, 1894) from an employment of hyoscin in five cases of hystero-epilepsy, comes to the following conclusions:

1. Hyoscin will abort an incipient attack and suppress one which has developed.
2. In most cases it produces sleep.
3. Its action will follow in five to twenty minutes.
4. One milligram is on an average, sufficient.
5. No important disagreeable symptoms were observed after such doses.
6. If employed for some time there is no accustomation to its action.

TREATMENT OF ACCIDENTS FROM ELECTRIC CURRENTS OF GREAT INTENSITY.

Dr. D'Arsonval (*Deutsche Medizenal-Zeitung*, No. 63, 1894) reports a case of shock from an electric current of great intensity, such as is used for illumination. Experiments on animals have demon-

strated that such cases may be saved i artificial respiration be applied at once even though the current be very strong. The condition in question is asphyxia and syncope, states where something can be done. The criminals which have been electrocuted in America, he claims were only apparently dead for they received only 1500 volts; in his experiments he employed one of 2500 volts. He accidentally had an opportunity to test the value of his deductions. On an electric railroad a current of five hundred volts was used with one hundred and ten interruptions (800 milliampères). A workman unconsciously placed himself into the circuit and received the full strength of the current. For five minutes he was exposed before it could be cut off. It was forty minutes before medical aid arrived. Though he was thought to be certainly dead, artificial respiration was begun and later rhythmic tractions of the tongue attempted—Laborde's method. Respiration gradually recommenced; he was transferred to a hospital where he returned to consciousness and is now under treatment for the burns. Another workman who came to the unfortunate man's aid also received a shock but without serious injury. The former was an epileptic.

USE AND MISUSE OF BICARBONATE OF SODA.

Dr. Rosenbach (*Centralblatt f. d. Medicinischen Wisssenschaften*, No. 30, 1894), claims that the bicarbonate of soda is prescribed by far too often to neutralize excess of acid in the stomach. It is, except in extreme cases, difficult to determine whether the excess of acid is abnormal. To determine whether the excess of acid is the real cause of stomachic disturbances, a careful consideration of the patient's occupation, his general condition, feces, nutrition, the consistence of the stool, etc., are necessary. In too rapid eating there is prone to be a faulty relation of motor functionability and production of acid. Formation of organic acids—fatty or lactic acid—may be a cause. Thirdly and most frequently, the dyspepsia is due to pure hyperesthesia of the organ. On account of its sedative action the bicarbonate is often misused and in too large doses; not more than a good sized pinch should be taken at one time. Frequently a piece of dry bread or biscuit will suffice to absorb the excessive acid.

TREATMENT OF HEMATOPORPHYNURIA.

Dr. F. Mueller (*Wiener Klinische Wochenschrift* No. 14, 1894,) had under observation a grave case of hystero-neurasthenia, in a woman who, for five months, took a gram of sulfonal every day, on account of sleeplessness. At the end of this time she commenced to pass a dark brown urine containing hematoporphyrine while her strength and mental powers began to deteriorate rapidly; her pulse was filiform. The hemameter showed that the hemoglobin of the blood had sunken to less than half of the normal quantity. At the same time there was obstinate constipation and scanty urine. The hypnotic was discontinued without result, but a daily dose of five to eight grams of the bicarbonate made a decided improvement. This latter drug was given on account of the great acidity of the urine and the corresponding decreased alkalescence of the blood. Three weeks later the bicarbonate was discontinued for a time, but the hemotoporphynuria reappeared in four days. Given again, the acidity of the urine disappeared, the hemoglobin became normal and after its use for several months the neurasthenia was greatly improved. Also, in a second case, tabes dorsalis, where hematoporphynuria was caused by sulfonal, alkaline treatment caused this symptom to disappear. The patient had taken from one-half to one gram of the drug per diem, for two months.

Dr. E. Schultze, (*Deutsche Medicinische Wochenschrift*, No. 7, 1894), also has observed hematoporphynuria in a case of melancholia in a woman with obstinate constipation, after the use of trional, in a daily dose of one-half to one and a half grams, for four weeks. The urine was of a dirty reddish brown color. Chemical and spectroscopic examination revealed hematoporphyrine to be present. A few days later death followed, with symptoms of rapid dissolution. The small dose compared with that of sulfonal, is worthy of note. Trional is offered as a substitute for sulfonal.

PAIN AFTER EXTRACTION OF A TOOTH.

In the *Revista Medico-Quirurgica Americana*, July, 1894, the following mixture

is recommended in pain after extraction of teeth:

℞

Morphine	o	30 (grs. ivss.)
Tr. Aconite		
Chloroform		
Alcohol ãã	30	o (℥j.)

This formula is especially valuable when the pain continues for several days, as it is sometimes liable to do. Apply locally on a ball of cotton. A mixture of equal parts of chloroform and tincture of aconite, or one containing one part of camphor dissolved in two of chloroform is also praised, in the same condition.

A CASE OF MELANOMA CURED BY ARSENIC INTERNALLY.

Prof. Lassar (*Deutsche Medizinal-Zeitung*, No. 64, 1894), recently presented before the Medical Society of Berlin, a case of malignant melanoma in a woman where a definite cure was obtained by the internal use of arsenic. A nodule had developed beneath the nipple and which was probably due to pressure by one of her corset stays. The little growth had been cauterized, but it returned in a few weeks and grew to the size of a cherry. Any further operative interference, even excision of a piece for histological examination being refused, Fowler's solution was administered in a dose of five drops, three times a day, after meals. The growth commenced to decrease in size and to shrivel up from the very first week. The remedy was discontinued, at times, but the tumor ceased to decrease and even showed tendency to progress until, finally, this year she completed the treatment with an entire disappearance of the tumor. Two months have elapsed since then and no signs of a return have been remarked. He claims that by the early internal administration of arsenic, it is possible to bring a favorable influence to bear on such heteroplastic growths. On account of the great malignancy of melanomata, the ease with which they recur and their rapid generalization, they are among the most feared of cancerous new growths. He claims that no case is known in the literature that has been cured, without an operation. Their general tendency is to progress to a fatal termination even though they remain quiescent for a time. In the case reported, a benign nævus increased in size during the "course" of treatment.

HORDEOLUM.†

Ripault (*Gaz. Med. de Paris*, June 30) remarks that Hordeolum, that small furuncle which springs from the base of the lashes, seems scarcely worthy at first view of a moment's attention; nevertheless, as it gives rise at times to grave errors of diagnosis it is worth while to study its nature and characteristics.

Etiology.—A stye may appear abruptly in a subject whose lids and conjunctivæ are quite healthy; it then comes from a purely accidental inoculation, and has every chance to remain isolated. Ordinarily it is found in lids that are more or less diseased. The patient is suffering from an acute blepharitis, or one that is becoming chronic; the palpebral borders are red, excoriated, thickened, the seat of intense itching; the lashes are agglutinated, or have fallen away in places; superficial at first, the infection increases in depth towards the glandular zone. In certain cases lesions of the glands of Meibomms may be noted; small yellowish tracks appear on the conjunctivæ, clearly inflamed in their central points. Finally this furuncular blepharitis which especially limits itself to the lower lid, will be associated with lachrymal conjunctivitis so often unrecognized, but described by Galezowski in particular.

Stye is most common in eyes affected with conjunctivitis, or with strumous kerato-conjunctivitis; children are more readily exposed to it when they have contracted the bad habit of rubbing energetically the lids night and morning, or during the day to relieve the itching. Vices of refraction also occasion it; it may also be produced by the clasp of glasses, the use of magnifying lens, the use of the microscope and by rubbing. Certain professions peculiarly expose the patient to the disease on account of the occular irri-

† Translated for THE MEDICAL AND SURGICAL REPORTER, by W. A. N. Dorland, M. D.

tation produced; the dust of mills, of grain, of charcoal, may readily produce a stye. Women and young girls may be affected with it at each menstrual period; sexual infection is an undoubted source of the disease. Finally the furuncular diathesis is essential to the production of stye.

Pathologic Anatomy.—This is based entirely upon that of any furuncle, and presents nothing of special interest.

Symptoms: Its onset is always abrupt, with more or less intense itching, with finally a slight pain like the pricking of a pin. There then appears on the free margin of the lid, a small red point which becomes pronounced and shows a tendency to spread. Winking movements are very disagreeable and are rendered more difficult; if the small, inflamed surface be touched, one provokes an acute pain against which the patient involuntarily defends himself. Usually at the end of three or four days, there is experienced a severe tension accompanied by slight paroxysmal lancinating pains indicative of suppuration; the tumor increases in size and at its summit may be noted a characteristic small yellow spot; when this is discharged the tumor quickly disappears and cicatrization is rapidly accomplished. The general phenomena are slight or absent; at times there will be some malaise and anorexia; there is no true fever. The stye may be single and absolutely ephemeral, but this is not the rule. Ordinarily there will be found two or even several in different stages of development upon one or both lids. Often there will be an uninterrupted series of these furuncles tormenting the patient during weeks or months; these relapses constitute the principle discomfort to the affection. The *diagnosis* is plain.

The *Treatment* consists in applications of repeated antiseptic compresses; then as soon as pus has formed, an incision should be made with a small bistoury; a slight digital compression will aid in the discharge of the matter. To prevent the return of the disease, antiseptic pomades may be used each night, such as vaseline 5 grams and yellow oxid of mercury 5 centigrams; tepid lotions, morning and night, with saturated boric water are of service. The preventive treatment will be based upon the diagnostic etiology; the general state must not be neglected; local and general prophylaxis is essential.

BACTERIOLOGICAL NOTES.

CULTIVATION OF THE TETANUS BACILLUS.

Frothingham, (*Am. Jour. Med. Sci.*, May, 1894,) gives the results of his investigation into the methods of cultivating the *tetanus bacillus*. The difficulties attending the cultivation of this organism in pure culture are met with in its isolation from the other organisms with which it is usually associated in the infected wound. Although it is an anærobic bacillus it is not difficult to cultivate it after it is obtained in pure culture. Many methods have been suggested for the isolation of this bacillus, several of which the author reviews. The method suggested by the author, he believes may be of practical use in the diagnosis of tetanus in certain suspected cases of traumatic origin. Without entering into a discussion of his method of obtaining pure cultures of this organism from traumatic origin or from experimental animals, a summary of process is given.

1. "Inoculate alkaline bouillon with the pus from the wound, or, pus being absent, small bits of tissue from inside of the wound, or in experimental animals inoculated with pure cultures, bits of tissue from the regions of the point of inoculation are used.

2. Place tubes in an atmosphere of hydrogen and in the breeding oven for forty-eight hours.

3. Examine microscopically, and if tetanus bacilli are present,

4. Heat from three-quarters of an hour to an hour, in water-bath previously heated to 80° C.

5. From heated tubes inoculate fresh bouillon and place in thermostat under hydrogen for forty-eight hours.

6. Test purity by microscopic examination and make cultures in gelatin, agar, etc.

7. Test virulence on mice, white or gray.

A NEW STAIN FOR GONOCOCCUS.

The importance of a satisfactory method for staining gonococci is obvious in certain doubtful cases of suspected urethritis. Lanz (*Deut. Med. Wochenschrift*, 1894, No. 9), recommends the following method:

A cover-glass preparation, made in the usual way from the secretions, is immersed for from one-half to two minutes in a 20 per cent. solution of trichloracetic acid and washed in water. It is then placed in the stain for from three to four minutes. The stain used is made as follows: 30 cc. of water, 1 to 2 drops of a 5 per cent. carbolic acid solution and saturated alcoholic solution of methylene-blue in sufficient quantity to give to the liquid a deep blue color. After staining the preparation is washed in water, dried in the air and mounted in balsam, or examined at once in water. The gonococci are said to be very nicely stained and clearly differentiated, as the acid used has the effect of preventing the protoplasm of the cells from becoming deeply stained. The author also states that a beautiful double stain may be obtained by after staining with Bismarck-brown.

THE EFFECT OF THE TOXINES OF ERYSIPELAS AND BACILLUS PRODIGIOSUS ON INOPERABLE MALIGNANT TUMORS.

In 1892, Dr. Coley of New York, published a paper on the treatment of malignant tumors by repeated inoculation of erysipelas. Although measurably successful the method has been changed to the use of the toxines of the streptococcus of erysipelas and *bacillus prodigiosus*, obtained from pure cultures of these bacteria. In the July number of *The American Journal of Medical Sciences* Dr. Coley has given the results of his investigation with these toxines and the methods used in their preparation. He summarizes his results as follows:

1. The curative action of erysipelas upon malignant tumors is an established fact.
2. This action is much more powerful in sarcoma than carcinoma.
3. This action is chiefly due to the toxines of the erysipelas streptococcus, which may be isolated and used with safety.
4. This action is greatly increased by the addition of the toxines of *bacillus prodigiosus*.
5. The toxines to be of value should come from virulent cultures and should be freshly prepared.
6. The results obtained from the use of toxines without danger are so nearly equal to those obtained from an attack of erysipelas that inoculation should be rarely restored to.

PALIATIVE TREATMENT OF UTERINE CANCER.

In cases where operation is impracticable as the malignant deposits cannot be removed entire, Boldt (*British Medical Journal*) recommends as the best form of treatment curetting and subsequent cauterization. Curetting and packing with pledgets saturated with chloride of zinc also proves beneficial. If rigid antiseptic precautions be taken piercing of the uterus by the curette may do no harm. The uterus is curetted, then the cavity is sponged with a mixture of commercial acetic acid (1 drachm), glycerine (3 drachms), and carbolic acid (20 grains.) Lastly the cavity is packed with absorbent wool.

Papoid in Diphtheria.

Dr. J. Lewis Smith, of New York, recommends papoid in diphtheria, after an experience in sixty-three cases. He first cleansed the surface with a spray of hydrogen peroxide, and then applied the papoid in the form of a powder.

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

HAROLD H. KYNETT, A. M., M. D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Asbury Park, N. J.—1026 Arch Street, Philadelphia, Pa.

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, OCTOBER 6, 1894.

EDITORIAL.

THE CAUSATION OF CANCER.

What may be the agent directly the causation of cancer, what its nature and life history, is a problem that, thus far, has eluded all attempts at solution. The experiences of clinical observers accumulated through centuries, had made the medical profession thoroughly familiar with the symptoms and physical signs of the dreaded disease; but this knowledge concerned the results rather that the causation of cancer, and little progress had been made toward successful treatment. Many and divers theories were put forth to account for its existence; none were able to meet all the conditions required, and cancer was accepted as a disease incurable.

The advent of the microscope practically created scientific pathology. The use of instruments of precision rendered possible greater progress toward solution within a decade, than had been accomplished during all the centuries preceding. Pathological anatomy has informed us of the elements, structure and evolution of the morbid condition. It has shown us what cancer is. It has not made manifest its primal cause. The objective has taught us what is the most valuable and accurate of our pathological knowledge. But investigation has now attained a point beyond which the microscope can not penetrate, and other methods are necessary to supplement and complete its revelations. We have learned nothing as to the causation of cancer, nothing as to its prevention, nothing as to its cure. Despite our boasted enlightenment where cancer exists, should metastasis have occurred, the most radical operation of the boldest surgeon is of no avail. Cancer is still classed as a disease incurable.

In this epoch of micro-biology, it is both natural and rational that researchers should apply to cancer those theories which have appeared most satisfactory in the investigation of other diseases, and to regard cancer as a disease of microbic origin. The theory is plausible. It satisfies more of the conditions presented by the disease, than has any other theory thus far advanced. It develops directly the clues given by the microscope. If thus far it has failed of proof, on the other hand it has not been disproved. That cancer presents conditions widely differing from those presented by other diseases

which we now accept as of microbic origin, does not militate against the assumption of such origin. It appears to be analagous to diseases which we know are dependent upon infection with parasites. The most advanced of modern experimenters and observers tentatively catalog cancer as a disease of parasitic origin.

It must be remembered, however, that the "parasitic causation of cancer" accepted as a working hypothesis is one thing, and the "parasitic causation of cancer" accepted as a demonstrated fact, is very different. To seize upon an immature hypothesis and proclaim it as a dogma, is an act of unmitigated folly. The disastrous consequences of such folly have repeatedly been brought home to this generation. It is hardly necessary to mention the cure of consumption by sulphuretted hydrogen, or the rejuvenation of mummies by the elixir of life, or the more recent annihilation of tuberculosis by tuberculin. Similar fads exist today, and still they come. As a working hypothesis, the parasitic causation of cancer is acceptable. But until the theory depends on something more than inference, it is not a proper basis for scientific treatment. The subject is *sub judice* and the testimony of all credible witnesses must be heard and given consideration.

In this connection a report to the British Medical Association, of the results of careful experiments and observations, made by Mr. D'Arcy Power, (*British Medical Journal*), is of interest. This observer assumed that a protozoon was present in cancer, and endeavored to trace it from the tissue forwards into the soil, and thence onward into the animal. His experiments were conducted under conditions approaching, as nearly as possible, those which clinical experience have shown most favorable for the production and development of cancer. The hypothetical protozoon was assumed to be transmitted either through the agency of the soil, or of insects, or possibly through that of water. Selected specimens of soil from localities remarkable for high mortality from cancer, as shown by statistical returns, were prepared in such manner as seemed to fulfill all the conditions for the successful propagation of cancer, if, perchance, there was a cancer organism, and if a part of its life was passed in the earth. Cages of open wire work were put upon the prepared soil, and white rats were placed in the cages so that their feet and tails remained in constant contact with the earth.

Assuming that cancer is produced by an organism, that organism must gain access to the body, unless it be held that the host was born with the germ—an untenable hypothesis. The only ways in which such a parasite could effect entrance into the body is by the respiratory or digestive tracts, by direct inoculation of a wound, or by implantation into the skin or mucous membrane. It has been shown that the healthy uninjured skin of men and animals is permeable to microbes, which enter between the sheath and shaft of the hairs; but not through the orifices of the sweat and sebaceous glands. It has been shown that cancer cannot be produced by feeding experiments. The author's own results prove that it cannot be produced through the mucous membrane. The great difficulty of inoculation from without has been demonstrated, and what would seem positive results in such external inoculations, are not above criticism. It seems therefore that cancer might possibly enter the body through the respiratory system and then pass to the tissues most suitable for their growth and development, as in the case of many infective organisms. On this account the rats were frequently sprayed with cancer pulp, and throughout the experiment care was taken to keep the mucous membrane of their vaginæ in a state of slight but chronic irritation, so as to provide a point

of least resistance. Six rats underwent the same treatment.

Mr. Power relates:—

"They lived upon the soil for about eleven months each; four were killed, and two died, one from cold, and the other, at post mortem examination was found to have a large tapeworm lying free in its peritoneal cavity. A careful necropsy was made in each case, but in no instance could a trace of cancer be detected in any of the organisms or tissues either by the naked eye or microscopically. The lungs of two of the rats which had been subjected to the spray were found to be shrunken, and their edges were studded with dense white nodules. The center of each nodule was softer than the outside, and consisted microscopically of round cells of the type of ordinary granulation tissue, whilst the external portion was formed of the pulmonary alveoli blocked with cells apparently derived from the epithelial lining. There was a considerable quantity of extravasated blood in the vesicles, and the red corpuscles were in many cases undergoing disintegration. Numerous spheroidal and granular cells, such as are common in irritated epithelium, and exactly resembling those found in the segmentation cavity of an incubated hen's egg, lay in the blocked vesicles. They were in all probability eosinophile leucocytes. The deeper portions of the cortex of the nodule consisted of newly-formed fibrous tissue. The explanation of these appearances in the lungs seems to be that as a result of the irritating action of the spray, or of substances introduced by the spray, there was congestion leading to an extravasation of blood into the alveoli; farther irritation led to multiplication of the epithelial cells lining the pulmonary alveoli; finally there was a fibrillation and contraction of the newly formed inflammatory products. In other words, there were set up all the changes leading to the condition known as 'pseudo-tuberculosis,' the results of a defensive or phagocytic inflammation."

Mr. Power, continues:—

"Another question which arises out of a consideration of the etiology of cancer is, How is the disease distributed? The conclusions arrived at by Surgeon Hehir and by the great Italian school of scientific medicine in regard to malaria appear to have a certain bearing upon this question. Ague certainly, and cancer possibly, are produced by specific organisms of the nature of protozoa, which gain access to the body from without."

"The disease cannot be inocu lated in either case or, in other words, in neither disease does the organism when once it has been introduced into the body, leave it again in a condition fitted to reproduce the disease. Malaria however differs from cancer in its termination. In malaria there is no tendency on the part of the parasite to kill its host; in cancer the disease usually progresses steadily towards a fatal issue. This at once marks a difference between the two organisms and it may lead to a better knowledge of the distribution of these diseases. In a very able paper, which appeared in the *St. Thomas's Hospital Reports*, for 1892, entitled Specific Diseases Considered with Reference to the Laws of Parasitism, Dr. Payne points out (p. 86) that if death is a usual or frequent consequence of any parasitic disease, it raises the presumption that the vitality of the infecting organism is not destroyed, or even that the continuance of the species may be favoured by this event. Many difficulties at once offer themselves in regard to the parasitic theory of the origin of cancer if it be considered from this standpoint. The disease is too exclusively human for any wide distribution to be effected by the disintegration of the host's body such as takes place in anthrax, the plague, or typhus. It is possible to assume that the hypothetical protozoon causing cancer is only one stage in the alternation of generations which is so frequent in the lower forms of animal and vegetable life, and it is this point which I have endeavored to elucidate, but so far without success. It is of course possible, too, to assume that the cancer germ is exclusively human in its proclivities, as appears to be suggested by the case with which Hahn and von Bergmann are reported to have transferred cancer from one part to another of a cancerous patient's body, though here again their experiments are open obviously to another interpretation."

"The 'cancer organism,' which was described by Dr. Ruffer in his earlier papers, appears to be exclusive human in this sense, for after grafting cancer, upon the irritated mucous membranes of animals I have succeeded in obtaining appearances which resemble these bodies, and which I have not yet found as a result of the simple irritation of tissues, or after the grafting upon them of such normal epithelial cells as those on the anterior surface of the cornea. In the rabbit the structures resembling Ruffer's 'cancer bodies' are intracellular, and are also found between the cells, but they entirely disappear within a week of the introduction of the cancerous tissue, and I have not yet ascertained what becomes of them. They are perhaps, destroyed by the cells which they have invaded. If this be so, and assuming that such bodies are the cause of cancer—an assumption which is still gratuitous, for it has to be proved—we have an explanation of our inability to produce the disease artificially in animals. It may be that the 'cancer bodies' are merely phases in the degeneration of cells, and that, as the changes become more marked, these striking appearances disappear."

"The result of my experiments is negative as regards the propagation of cancer, but interesting preparations have been obtained showing the various forms of cell degenerations. Many of these degenerated cells have been described by different writers as parasites. They are met with, in normal epithelium which has been slightly irritated, and I am therefore bound to confess myself an unbeliever in any of the 'cancer bodies' which have yet been discovered. No evidence has been adduced to show that they are other than the results of cell degenerations, modified, it may be, by the conditions under which they occur, but not differing essentially from the changes which take place in cells as a result of chronic irritation. The cause of cancer has still to be discovered."

ABSTRACTS.

NEW MEANS OF LOCAL ANÆSTHESIA.

One Dr. K. L. Schleich, of Austria, claims to have discovered that absolute immunity from pain, even during protracted operations, may be obtained by subcutaneous injection of a sugar or salt solution, or of merely cold distilled water; that the results induced are to all intents and purposes identical with those obtained by like employment of cocaine. He adds:

The patient may remain perfectly conscious during the amputation of hand and foot without undergoing the tortures so often inflicted upon the battle-field, or the exceptional dangers of syncope ever present in the operating-room when general narcosis is resorted to.

It is declared that this discovery has already borne the test of several experiments and is about to be applied in the hospitals of Vienna. The explanation of the phenomenon is:

Local insensibility to pain is induced in the case of cocaine by purely chemical changes, while cold water or solutions of sugar and salt act mechanically through high pressure and low temperature. Under the influence of high pressure and sudden low temperature the blood and lymph are driven from the places operated upon, to where the pressure is less. The tissues are thus deprived of their supply of blood, and temporary paralysis of nerves results.

The foregoing seems to have met with favor in numerous quarters, and in one instance at least a surgeon of authority affirms that "its importance is all the more undoubted, seeing that if in a given case cold water alone should fail to produce the needful degree of insensibility, a weak and absolutely harmless solution of cocaine would prove certainly efficacious."

Whether true or false, it is hardly probable that surgeons will give up the use of cocaine, which is deemed certain, in favor of a method which will always be apt to carry with it a feeling of indefiniteness.—*Medical Age.*

FEVER.

With development of our knowledge of the acute infectious diseases has arisen the theory that the fever occurring as a part of their clinical picture is the result of the action on the body of certain diffusible products of bacteria which are their cause. With a view to adding definiteness to this theory, Centanni (*Deutsch. med. Woch.*, 1894, Nos. 7 and 8) was undertaken an exhaustive study of the fever of the infectious diseases, his investigation being directed to the determination of the following points: (1) What are the agents which cause the fever in these diseases? (2) What is the mechanism by which they act? (3) What therapeutic deductions are possible from the facts developed? The work is not yet completed, but a number of facts bearing upon the first question have been discovered, and form the basis of a preliminary paper upon the "Fever-producing Poison of the Bacteria."

The investigation extended to seventeen pathogenic species, seven non-pathogenic, and to cultures made from air, water, putrefying animal matter, and urine, without any attempt to separate or identify the several species. From cultures of these germs, *devoid of peptone*, Centanni obtained, by repeated precipitation with alcohol and dialysis, a substance whose chemical properties are quite distinct from those of the bacterial poisons heretofore described (ptomaïnes, enzymes, toxalbumins), which, when injected into animals, causes fever, prostration, loss of flesh, and finally death, if continued. This substance, which Centanni believed to be the same in all species of bacteria, is designated by him "pyrotoxina bacterica." It is believed to be in some way derived from the protoplasm of the germs, or to be elaborated by it, and its production is thought to be a quality of all bacteria. He is led to believe that the fever

accompanying the acute infectious diseases in man is due to an intoxication of the system by this poison, and explains the irregular course of the fever in the different diseases by the theory that the poison depends for its elaboration upon variable conditions, and that it is these conditions which are different in the various diseases, and at different times in the same disease, not the poison.—*Am. Jour. Med. Sci.*

THE SUBLINGUAL ADMINISTRATION OF HYPODERMATIC TABLETS.

Dr. Paulson writes *The Lancet* (London) that he has found a new use for hypodermatic tablets, viz., their sublingual administration. They may in their entirety be placed beneath the tongue, or a solution made in the usual way and a few drops allowed to fall on this organ. He asserts that the medicament thus placed will exhibit its physiological effect almost if not quite as quickly as if employed subcutaneously, particularly if one takes into account the time essential to prepare the syringe before the injection.

It is somewhat curious, if Dr. Paulson's statements are true, that such a method of administering potent remedies should have been so long overlooked; and yet it apparently has a basis of rationality from the fact that beneath the tongue is a large surface covered with thin transparent membrane nourished by a great number of vessels of considerable size, and, moreover, particularly rich in distribution of active absorbents.

There are many cases in which the sublingual method of administration would doubtless be found of infinite service and often preferable to the hypodermatic, not the least of which is the absence of unfavorable impression often created upon the mind of the patient by the latter method. If the inefficiency and celerity of sublingual medication are all that is claimed, it certainly should be wider known and come into very general use.

Another advantage is avoidance of the difficulty oftentimes encountered in employing powerful remedies by the stomach —this organ may be "in a state of rebellion," secreting mucus to shield its irritated membranes, and contracting frequently to relieve itself, consequently one can know little of what proportion of a remedy thus introduced will be absorbed and what proportion merely serve to increase the aggregation of excretion and waste. On the contrary, by sublingula administration the practitioner is not only certain of the dose, and that it will be absorbed within sixty to one hundred and twenty seconds, but is assured of the full physiological result in about ten minutes to a quarter of an hour. Certainly this simple plan is worthy of trial, and we should be very glad to hear from medical men as to the results obtained. It is said that a tablet of pilocarpine introduced under the tongue acts even more quickly and profusely than when employed hypodermatically. Moreover, there is no hypodermatic tablet, satisfactory in composition for use in the syringe, but what should, if all Dr. Paulson claims is true, be equally available and effective when employed sublingually.—*Medical Age.*

Pasteurized Milk.

Pediatric authorities advise that all milk fed to children should be pasteurized in warm weather—that is, raised to a temperature of 168° F., to destroy ferments and prevent souring. This temperature kills tubercle bacilli, typhoid and other germs that may be present in the fluid. It is true that it also renders the casein of the milk less easily digestible, destroys milk-sugar, and causes proteid matter to adhere to fat globules, thus retarding their digestion; but these results are of little importance clinically, except in the case of weak children, while the benefits are many and obvious.—*Jour. of the Amer. Med. Ass'n.*

Gonorrhœa.

Dr. Edward Martin, of Philadelphia, prescribes:

℞ Balsam capaiba..... .....
Oil sandal-wood..... .....āā mv
Oil cinnamon..... mj

In capsule. Of these he gives 6 to 12 daily, administering them one hour after meals.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D., AND SAMUEL M. WILSON, M. D.

THE BRITISH JOURNAL OF DERMATOLOGY

for September contains an illustrated article on

The Function of the Sweat Glands in Man,

by Dr. P. G. Unna.

Describing his theory and experiments by which he proved it at length, the author concludes that "the ordinary sweat glands in man secrete fat, which at any time can be proved both on sections of the skin and in the sweat of the hand, by means of treatment with osmic acid—a fat which, though similar to that of the sebaceous glands, is different from it as stearic acid and margaric acid are from oleic acid."

Dr. Malcolm Morris discusses the

Management of Eczema.

The author thinks that as a general rule the less internal remedies we use the better, but that if a constitutional dyscrasia be recognized it must, of course, receive appropriate treatment.

When the skin lesions are acutely inflammatory the use of antimony seems beneficial, and the author gives ten or twelve minims of wine of antimony, repeating the dose in an hour, and, if necessary, in two more. Gradually the interval is increased and the dose lessened until six minims are given three times daily, and this is continued until the inflammation subsides. Arterial tension is an indication for the use of this drug, and depression a positive contra-indication.

Deficient strength and nerve force may call for strychnia, arsenic, belladonna, phosphorus, quinine, etc., but the author thinks diet has only an indirect influence, through its effect on digestion, the general health, etc.

Every case is treated as though it were of parasitic origin, the objects aimed at being the destruction of micro-organisms, the protection of inflamed surfaces, and the relief of inflammation. In following this plan a weak antiseptic is used and the strength gradually increased. Two favorites with the author are sulphur and resorcin, because they not only kill micro-organisms but promote exfoliation of affected cuticle, and he usually commences with an ointment containing ten grains of one of these in an ounce of zinc ointment. When much inflammation is present ichthyol in some cooling "cream" is used.

The plaster mull of Unna, composed of carbolic acid, mercury and oxide of zinc, has been useful in chronic cases where the area affected was limited.

While change of climate is often beneficial, the personal idiosyncrasy plays such a prominent part that one must often choose as much with the object of making a change as for any special property the place chosen possesses.

Dr. Unna demonstrated the presence of more cocci in eczema, and finding that they grow only in the presence of free oxygen, proposes sealing the surface of affected parts, so as to exclude this gas.

Dr. Henry Standford reports a case of

Summer Eruption

somewhat resembling hydroa vacciniform.

THE ST. LOUIS MEDICAL AND SURGICAL JOURNAL

for September. Dr. A. H. Ohmann-Dumesnil advocates the application, on a small wooden spatula, of C. P. nitric acid to mucous patches of the mouth, pharynx, etc., as superior to most other methods of treatment.

Bone Marrow in the Treatment of Pernicious Anemia.

Dr. Thomas R. Fraser, in the *British Medical Journal*, has a very interesting article on the results obtained in pernicious anemia by giving bone marrow. The patient was a gardener, aged sixty years, and had the symptoms of frequent vomiting and diarrhea, edema of the feet and ankles, moderate and irregular pyrexia, dimness of vision, retinal hemorrhages, dyspnea, and latterly complete prostration. The hemocytes of the blood varied from from 1,860,000 to 1,460,000 per cubic millimeter, and the hemoglobin from 27 to 30 per cent, the specific gravity being 1038. There was great distortion in the shape and variation in the size of the hemocytes, which did not form rouleaux. Retinal hemorrhages were present in both eyes. The ordinary treatment of iron and arsenic was instituted and the examination of the blood showed further deterioration. In the fifth week ox-bone marrow was given by the mouth, uncooked, three ounces daily, in addition to the medicines. A rapid improvement ensued. The patient soon recovered strength and body weight, could remain out of bed and appetite was better. At the end of about four months the hemocytes remained at about 3,400,000, the hemoglobin averaged 70 to 75 per cent. and the specific gravity 1059. The patient felt strong and enjoyed doing light manual work. He had no subjective symptoms, and the "hemic," venous and cardiac *bruits* were no longer audible. After eight months' treatment the patient was discharged to return to his occupation as a laborer. The hemocytes were nearly uniform in size, only a few of them showing a slight "tailing" and no megalocytes were present, there was no excess of the leucocytes or of blood plates, and good rouleaux were formed on the microscopic slide. Inasmuch as it has been demonstrated by physiologists that the colored blood corpuscles are derived from the large, pale cells in the red marrow of bones, especially of the ribs, Dr. Fraser's treatment is especially happy in theory, and apparently successful in this one case.—*A. M. Practitioner.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

MEDICINE

Two Easy and Delicate Tests for Albumin in Urine.

Dr. C. Fouchlos (*Progres Medical*) recommends two new tests for albumin in urine, for which he claims utmost delicacy and absence of any possible fallacy.

1. Add to the suspected urine a few drops of a 1 per cent. solution of corrosive sublimate; in case of turbidity, add some drops of acetic acid. If the turbidity persists it is due to the presence of albumin.

2. Take 100 cc. of a 10 per cent. solution of sulpho-cyanide of potassium, and mix with it 20 cc. of acetic acid. Add a few drops of this mixture to the urine. If albumin is present in small quantities, an immediate turbidity will ensue; if in large quantities, a heavy white precipitate will appear.—*Med. Review.*

Stomach Washing in the Treatment of Alcoholism.

In an article on the treatment of the alcohol, opium and cocaine habits, Dr. Heine Marks, the progressive surgeon in charge of the St. Louis City Hospital, says in the *Courier of Medicine:*

In cases of acute alcoholism, where a quick restoration to a normal condition is necessary or desirable, I have devised a plan which has never failed to prove efficacious. This is simply washing out the stomach. The apparatus for this purpose consists of a glass funnel inserted in the end of a rubber tube leading into the stomach. Through this I pour plentiful quantities of salt water, until vomiting ensues and the stomach is thoroughly washed out. The patient is then placed in a hot bath and afterward immersed in cold water. In fifteen minutes he is comparatively sober and the next morning perfectly so, and steady too. By this device I have been able to dispense with salts, bromides, chloral and other drugs. This treatment arrests gastritis, and, in experienced hands, never fails of accomplishing the desired result, though in inexperienced hands it might be attended with great danger.—*St. Louis Clinique.*

Rubidium Iodide in Skin Disease.

Dr. Leo Leistikow, of Hamburg, has advantageously used the above salt in a number of cases of secondary and tertiary syphilitic lesions, as well as in a case of gonorrhœal rheumatism. In the case of syphilis complicated with valvular disease, the heart's action was not in the least influenced by the rubidium iodide. Altogether the rubidium salts have no toxic effect upon the heart like the potassium salts. The taste of the rubidium salt is not as disagreeable as that of potassium iodide.—*Medical Review.*

Spray for the Nose and Throat.

In Part Second of "Saunders' Question Compends," No. 14, second edition, just issued, Dr. E. B. Gleason recommends for the purpose of spraying the nose and throat the following formula:

℞ Antipyrin ..... grs. xvi
Aquae ..... f℥j

He says: A solution of antipyrin of the above strength, when sprayed upon the mucous membrane of the nose, pharynx or larynx, has the power of contracting the capillaries and producing an artificial anemia, which effect is maintained for three to five hours. The above solution may be used with the atomizer in all acute inflammations of the mucous membrane of the upper respiratory tract. When used after the application of cocaine to the interior of the nose it will maintain the contractile effect of that drug upon the rectile tissue for several hours when sprayed upon the nasal mucous membrane without the previous application of cocaine, it gives rise to a smarting sensation, which, however, quickly subsides. Applied as a spray within the larynx by means of an atomizer, it contracts the blood vessels of the laryngeal mucous membrane and diminishes secretion, cough and expectoration. It is extremely valuable as a remedy for the night cough of laryngitis phthisica, often securing a night's rest for such patients, who may be provided with an ordinary hand atomizer filled with a solution of antipyrin and instructed to inhale its spray as often as is required to control the cough.

A Hitherto Unnoticed Symptom of Diabetes Mellitus.

Dr. Unschuld (*Berl. Klin. Wochenschrift.*): It is a well-known fact that the diagnosis of diabetes is frequently made only after the disease has lasted for a long time. Years ago Unschuld called attention to three points which frequently mark the course of the disease, namely: (1) Chronic catarrhs of the stomach, especially nervous dyspepsia; (2) certain disorders of sensation in the abdomen, partly explained as hysteria, partly as hypochondriasis; and (3) albuminuria. Since then he has had opportunity to see many hundred cases of diabetes, and has found that one of the most frequent symptoms is cramps in the calf of the leg, a symptom to which hitherto no attention whatever has been paid. These cramps usually show themselves in the morning on waking up or during the night, rarely during daytime. If such cramps are found in persons who, at the same time, complain of weakness and a tired feeling in the morning, the urine should at once be examined for sugar.

The cramps seem to be in no connection with the etiological cause of the disease and

are found in all forms of diabetes. They have no influence upon the course of the disease and usually disappear quickly on the patient getting up and by massage. It is still an unsettled question what they are due to.

Quinine and Pregnancy.

Appended are the deductions from an exhaustive article on this subject in the *Indian Medico-Chirurgical Review* for February, 1894:

1. The existence of pregnancy is no bar to the administration of quinine.
2. For fevers and other affections during pregnancy in which quinine is indicated the effects of the drug are more marked than those of any other.
3. That abortion following the administration of quinine is either the result of the original malady or the effect of idiosyncrasy.
4. That allowing for an idiosyncrasy, in cases in which a tendency to abortion exists and in others as a matter of precaution quinine is best administered combined with a sedative (opium).
5. Hence the old-standing view of the action of quinine on the duration of pregnancy is not borne out by the clinical experience collected in the replies.

Sarsaparilla Must Go.

The general trend of the discussion of the medicinal value of sarsaparilla is that, like the Chinese, it must go The *Medical Record* voices the sentiment of a number of medical men in the following editorial comment:

The esteemed editor of the *Therapeutic Gazette* comes to the rescue of sarsaparilla, and says that it ought to be retained in the Pharmacopœia because it covers the taste of iodide of potassium. This would be rather a weak excuse, even if it were true. But it does not happen to be true, as any one can be convinced by a trial.

The *Gazette* further puts forth the weird hypothesis that sarsaparilla syrup promotes the action of iodide. We venture to say there is not a scintilla of clinical proof that this is the case. The most brilliant results from iodide have often been obtained by enormous doses, after small doses combined with sarsaparilla have failed.

The fact is that the legendary belief in sarsaparilla as a "blood purifier" promotes no end of quackery and useless drugging. Hence physicians, at least, ought to rid themselves of false notions about it.

Pernicious Anemia.

Stengel (*Therap. Gaz.*) says the rapidity of improvement following the use of arsenic stamps it as almost specific. He gives it in the form of Fowler's solution, beginning with two-drop doses, rapidly increasing it to ten drops, and then more slowly to fifteen drops or more. It should always be given after meals. He has seen symptoms of gastric disturbance more frequently subside than become aggravated from its use. Under no circumstances should it be pushed so far as to produce diarrhea. In addition, the patient is at first to be confined to bed, and the diet should be nutritious and easily assimilable. The deficiency of hydrochloric acid in the gastric secretion often requires it to be administered.—*Phila. Polyclinic.*

Treatment of Incontinence of Urine in Children.

Drs. Legendre and Broca (*Revue des Maladies de L'Enfance*), in managing this affection, advise:

1. Examination of the genito-urinary organs for phimosis, stricture of the meatus or hypospadias.
2. Catheterization of the bladder for diagnosis of vesical calculus (rare) or atony of the vesical sphincter.
3. To look for reflex causes—worms, pinworms or too acid urine. This first so-called non-essential variety differs from essential incontinence—incontinence of hysterics and epileptics.
4. Incontinence of central origin, accompanied by enuresis both day and night, and constant mental preoccupation. This form requires suggestive and psychic treatment. Wake the child frequently and have him sleep on a hard bed. Elevate the foot of the bed, avoid drinking in the evening, and educate the bladder to retain the urine during the day. Hydropathic measures, cold sitz baths and ablutions, the general douche, electricity to the hypogastrium and perineum, are indicated. Static electricity is said to act especially upon the sphincter, and may be combined with suppositories of belladonna. This same drug, in pill form, is also valuable. Then, also nux vomica, strychnine and ergot associated with iron, as in the following formula:

℞ Extr. nux vomica, Strychnine, (gr. 1-6) } .....āā 0.01
Extr. ergot, Tartrate iron and potash, (gr. ¾) } .....āā 0.05

For one pill. One to six a day.

The tincture of rhus aromatica has also been recommended from its empiric use (10–100 drops a day).—*Lancet Clinic.*

Treatment of Pruritus Ani.

Dr. A. Berger states that the following method immediately relieves the itching and causes a rapid disappearance of the eczema of the perineum and scrotum which frequently exists in these cases: A cotton pledget, two or three centimeters (¾ to 1¼ inch) in length and steeped in a 2 per cent. solution of hypochlorate of lime, is introduced into the anus. This pledget is allowed to remain until there is a slightly smarting sensation, when it is immediately withdrawn and the anal region washed with the same solution, taking care not to wipe it off afterward.—*International Jour. of Surg.*

A New Symptom Accompanying Enuresis Nocturna.

Sigmund Freund, of Vienna, describes a new symptom which frequently accompanies the enuresis nocturna of children. This consists of a hypertonicity of the adductor muscles of the thighs. It is elicited on an attempt to separate the thighs when the child is sitting with the lower extremities extended on an even surface; marked resistance to passive separation is felt and seen to depend upon involuntary contraction of the muscles named. The same resistance is felt on attempting to flex the leg on the thigh. The observer found no constant relation between the symptoms and the degree and obstinacy of the enuresis. It seemed to occur only with certain forms of incontinence. It is presumed by the author that the enuresis is to be explained by special hyper-innervation of the detrusor vesicæ similar to that that is evidenced by the hypertonicity of the muscles.—*Med. Mirror.*

Is Marriage a Failure?

The Census Bulletin recently published gives the first official data on conjugal life in the United States. It shows that almost three-fifths of our entire population are single, a little more than one-third married, and not quite one-twentieth widowed. The divorces constitute a small fraction at one per cent. The proportion of widows is nearly three times as great as of widowers, indicating that a greater portion of widowers remarry than widows, while figures show that divorced men have remarried to a greater extent than divorced women. The fact that women are, at an earlier age than men, prepared to try the mysteries of matrimony is also proved by the statistics, for while there were only twenty-three males under the age of fifteen who were married, the number of married females under this age was 1,411.—*Kansas City Med. Rec.*

The Specific Gravity of the Urine of the Insane.

After reviewing the labors of several alienists on this point and the variance in their results, Dr. Umberto Stefani, of Padova, made a careful investigation, and studied for one or more months sixty cases of mental diseases, with the following results: In all cases of acute insanity, independent of special forms, the specific gravity ranged from 1030 to 1040, and sometimes higher. If the form is of short duration, the specific gravity will fall as the psychic symptoms diminish, until it reaches the normal, or even lower. When the remission of the psychic symptoms is followed by an exacerbation, the specific gravity of the urine will again increase.

If the course of the disease is long and tends to become chronic, the density of the urine ordinarily will, after a time, commence to diminish until it reaches normal or falls below. In cases of imbecility, paranoia' senile dementia and paresis without spells of excitement, the specific gravity of the urine is not increased. But if continued frenzy and excitement develop, the specific gravity will increase to 1030–1040

The writer throws out the suggestion that in the examination of the urine we have an index, probably, of the prognosis and course of the disease. A table of charts, showing the exacerbations and remissions, adds to the interest of the paper.—*Rivista Sperimentale di Freniatria edi Medicina Legale—Buffalo Med. and Surg. Journal.*

SURGERY.

The Rational Treatment of Appendicitis.

Dr. W. G. Ashton, in the *International Journal of Surgery*, thinks the profession is divided into three classes as regards appendicitis. The first class look upon it as a purely medical disease; the second class are uncertain; and the third class believe that surgery alone is the only rational treatment of this disease. He wishes to show that no one at the beginning knows what course the attack will take, but he believes that all forms are dangerous to life. His conclusions are:

1. That it is impossible with our present means and methods of diagnosis to know the nature of the pathological changes taking place during the course of an attack of appendicitis.

2. That all forms of appendicitis are dangerous to life, as it has been demonstrated that germs pass through the walls of the appendix without the presence of either ulceration or perforation.

3. That surgical interference is indicated in primary and secondary attacks of appendicitis so soon as the diagnosis is clear.

4 That surgical interference is not advised during an acute attack of appendicitis, except when grave symptoms intervene, unless a competent surgeon is at hand. Under these circumstances the case should be operated upon after the so-called recovery.

Hemorrhage After Operations on the Nasal Septum.

Dr. A. C. Getchell, in the *Boston Medical and Surgical Journal*, reports several cases of serious hemorrhage after operations on the nasal septum, from which he concludes that:

1. Operations upon the nasal septum may be followed by hemorrhage sufficient to very materially affect the health of the patient.

2. The artery of the anterior (cartilaginous) septum may lie near the surface, be of considerable size, and if atheromatous may cause serious hemorrhage.

3. Operations upon the nasal septum in adults should be advised only after carefully considering the good to be accomplished and the possible risk incurred.

Treatment of Mammary Abscess.

Paul F. Munde (*The Int. Med. Annual*): My method is very simple, and its simplicity has required but very little modification since its inception. It consists in the proper selection of the case (viz., a fresh abscess, not an old, neglected necrotic cavity), a *large* flat, coarse bathing sponge, two large three-cornered cloths (unbleached muslin or very large square handkerchiefs, folded from corner to corner) or a broad, long roller bandage, a piece of oiled silk large enough to cover the sponge, and some large safety pins. The modus operandi is as follows: The patient presents herself with a large fluctuating abscess of the breast; this is opened by one moderately large radiating incision at the most dependent point, the pus is gently expressed, and the abscess cavity irrigated with a 1 to 10,000 bichloride solution or, what is probably just as good, plain boiled (sterilized) water, all of which is gently squeezed out, and the abscess cavity closed by gentle manual compression by the patient herself, while the other dressing is being made ready. The sponge, which has been previously thoroughly cleansed by boiling and has been freed from sand and other impurities, is now fitted to the shape of the collapsed breast by hollowing it out in the center with scissors so as to admit about one-half of the organ. It is then soaked in as hot water as can be borne by the hand, rapidly squeezed out in a towel, placed over the breast so as to entirely envelop it, covered with the piece of oiled silk, and then uniformly compressed against the thorax with the roller bandage or with the two three-cornered cloths, the first cloth being applied over the lower part of the breast and tied or pinned behind the neck, the other straight around the thorax. Compression should be as tight as the patient can comfortably bear. The other breast, I must not omit to mention, must be protected by a covering of cotton wadding. This dressing is left undisturbed until the next day, except, if necessary, tightening the bandages as they become loose. On the following day the whole dressing is removed, the sponge washed in hot water and reapplied as at first, and this procedure is repeated every day until the abscess is completely healed, which in my experience has seldom been longer than a week. Indeed, the cavity is usually closed after the third daily dressing; but to avoid possible pocketing of pus through uneven application of the compression, it is well to examine the breast carefully each time, and if such pocketing is found, either express the pus through the original incision or make a new opening. I have never had this to occur when I myself applied the dressing, for I have always been particularly careful to adhere to the indispensable axiom of success —that is *uniform, even compression of the breast from the periphery towards the center and from the surface toward the thoracic wall.* Nursing from the sound breast should be suspended until the sick breast is well. The author states that he has used this treatment in every *fresh* case of mammary abscess which has come under his observation in the last eighteen years, and in not a single instance has he failed to achieve a prompt cure.

Thombosis of Veins of the Lower Leg Following Operation in the Trendelenberg Position.

V. Strauch, Moscow (*Centralblatt f. Gyn.*), reports three cases of this distressing complication as occurring in nineteen celiotomies, one of the three being still further complicated by pulmonary embolism, from which the patient happily recovered. The author ascribed the condition partly to the use of ether instead of chloroform, but chiefly to the acute flexion of the leg in the ordinary Trendelenberg position, and now intends to use a table of his own device on which the patient lies with the pelvis elevated but the leg extended. In the same journal Czempin, Berlin, describes his table, which seems to accomplish this result very efficiently.—*Archives of Gynecology.*

Excision of the Initial Lesion.

The early cure of syphilis, if such a thing be possible, is greatly to be desired. Dr. Edmund E. King, in the *Medical News*, makes a plea for the excision of the initial lesion of syphilis. By the early excision he claims that the disease may be aborted and by a later excision the secondary symptoms are moderated. This excision must be done boldly and the cut edges made to unite by first intention. The system is probably infected subsequently to the development of the initial lesion. The lesion should be excised under the strictest antiseptic precautions and the edges cauterized with pure carbolic acid. In his paper he draws the following conclusions:

1. That the early excision of chancres—that is, within a few hours after their appearance —will abort the disease.

2. That the excision of any unhealed chancre will moderate the subsequent secondary manifestations.

3. That excision constitutes the cleanest, least painful and most scientific method of treating the lesion.—*Maryland Med. Journal.*

Cream of Tartar in the Treatment of Gonorrhea.

Dr. Oteri (*Journal de Medecine de Paris*) has employed the cream of tartar in 280 cases of gonorrhea, buboes, chancres and operations on the prepuce. On account of its mild action it is of service in urethral injections, even to five a day. It subdues the inflammation and arrests the discharge. It is possessed of eminent antiseptic and absorbent properties. In profuse suppuration in wounds or cavities with sinous or necrosing walls it will yield good results if applied locally. In buboes, chancres and syphilitic ulcerations, as well as in balanitis, he has found it a good local application. It is cheap, devoid of odor painless, and easily handled.—*Lancet Clinic.*

Diseases of the Heart Muscle in Typhoid and Scarlet Fevers and Diphtheria.

Romberg (*Deutsche Archiv. fur Klinische Medicin*) concludes that the highest grades of parenchymatous degeneration of the heart muscle are present by the end of the second week in typhoid fever, then slowly disappear in the later weeks; interstitial myocarditis begins mostly at the end of the second week, while in scarlet fever it begins mostly on the fourth day, becoming excessive in middle of second week; in diphtheria degeneration begins at the seventh or ninth day, and reaches its highest development at the end of second or beginning of third week, except the characteristic fatty degeneration of diphtheria, which begins often very late. During fever, irregularity and smallness of pulse and dilatation are marked; the best sign of the latter is the galloping rhythm. This is an important physical sign. Amount of urine is usually diminished, slight albuminuria with or without hyaline casts. A bad prognostic sign in diphtheria is a very slow pulse.—*Medical Fortnightly.*

Preparing the Hands for Obstetrical Work.

I have been for some time past, when called to a case of abortion or labor at full term, in the habit of first washing my hands in coal oil and then in warm water, the time occupied not being over three minutes. Time is often of great importance when hemorrhage is profuse, and as kerosene is to be found in every household, there is no time lost in procuring it. After preparing my hands in the above-described manner, I curette the womb with my finger-nail in incomplete abortions and manipulate it in any other way that is necessary without fear of sepsis. Petroleum is of a most penetrating and detersive nature; it will loosen a tap from a bolt in a few hours that has been rusting on it for years.

Coal oil was used by the Persians for illuminating purposes over two thousand years ago and may have been used in obstetrical practice also, but I have seen no mention made of it and I do not believe it is even now in general use, if used at all, for the latter purpose.—*Maryland Med. Journal.*

Fixation in Fractures into Joints.

Dr. Ansel G. Cook, of Hartford, advocates in the *International Journal of Surgery* the fixation of bones in the treatment of fractures into joints, and maintains that there is no fear of ankylosis. His conclusions and rules of treatment are:

1. That bony or serious fibrous ankylosis is the result of injury and subsequent inflammation and not of immobilization.

2. That early passive motion only disarranges the fragments of bone, thereby increasing the production of callus, that it irritates the injured ligaments, and, by increasing the inflammation, tends to produce the ankylosis it is thought to prevent.

3. Immobilization is useful *only* when active inflammation is present, or until the ruptured ligaments and broken bones have thoroughly united.

4. The logical treatment of a fracture into a joint, therefore, should be rest and local applications to reduce inflammation. Reduction of the fracture as early as possible, then immobilization until the bones and ligaments have united (from three to eight weeks, or more, according to circumstances).

5. Passive motion, massage and use till the tissues become normal, or, if the massage fails, complete rupture of all adhesions under an anesthetic. The factors which will ultimately determine ankylosis are the nature of the original injury, the character and duration of the subsequent inflammation, the destruction of bone and cartilage, cicatricial contraction of the soft tissues around the joint, and the age and condition of the patient.—*Maryland Med. Journal.*

OBSTETRICS.

Chloral Hydrate in Labor.

Chloral hydrate, says Dr. John E. Gardner (*Lancet*), has a great effect in assisting dilatation of the os uteri and relaxing the rigidity of the perineum. No post-partum hemorrhage follows, nor is there any delay or difficulty in the expulsion of the placenta. The chloral, I think, might take the place of chloroform, if given in a small repeated dose during the long and tedious labor of the primipara. It does not seem to diminish the expulsive power of the pains, as I have often noticed in chloroform cases. I submit that the chloral might be further tried in place of chloroform in primiparæ in order to relieve the rigid perineum and so avoid having to use forceps. Chloroform, in my experience, is attended with a great tendency to post-partum hemorrhage, which I have never seen after the use of chloral in labor. For many years, I have from time to time experienced its boon to the poor, worn out and anxious mother, despondent with fear. After a dose of the chloral the frenzy passes off, and the patient settles down to her travail, which has a happy and speedy result.—*St. Louis Clinique.*

Superfœtation.

Dr. E. C. Boyle, in the *Charlotte Medical Journal*, reports that after delivering a woman at full term, and expelling the placenta by Crede's method, there followed, in a separate sac, a fœtus apparently three or three and one-half months old. The two placentæ were apparently attached to each other at their margins by a substance resembling the jelly of Wharton, but the circulation in each was independent—there was no anastomosis between the vessels. Both the fœtus and its placenta were normal.

Fetal-Placental Circulation During Parturition.

Caviglia (*Nouvelles Archives d'Obstet.*), after a series of careful observations, has arrived at the following conclusions:

1. Blood passes from the placenta to the child, during the process of birth, through uterine pressure, retraction and sometimes contraction.

2. The constant positive pressure of the fetal vena cava superior forms a resistance opposed to the passage of placental blood by the fetal organism. This resistance is inferior, however, to the force acting upon the placenta and is not sufficient to prevent the afflux of blood.

3. Respiration takes away cardiac force and blood from the systemic circulation, hence it diminishes venous pressure and the special resistance referred to in the second conclusion.

4. The afflux exists but to a slight extent in cyanotic asphyxia, owing to the high blood preesure in the venous system of the child.

5. The arrest of the fetal-placental circulation does not depend upon the diminution of pressure in the fetal-arterial system, but on the occlusion of the placental capillaries by uterine pressure. When the placenta is expelled early the pulsation may continue almost indefinitely.

6. The passage of blood from the placenta to the new-born child often continues after the umbilical arteries have ceased to beat.

7. During the first moments after birth the child's weight occasionally diminishes, on account of relaxation of the uterus. Too early ligature, therefore, involves the risk of removing from the child's circulation not only all the reserve blood, but also some of the blood necessary for the child at any given moment.

The two last conclusions are important in practical obstetrics.—*Archives of Gynecology.*

Diagnosis of Pregnancy.

Lawson Tait, in a clinical lecture, points out the great difficulties experienced in obtaining truthful and correct histories from illegitimately pregnant women, and the great caution to be exercised by the obstetrician examining such patients. Several interesting cases are reported from his great experience, in which he himself and others have had but narrow escapes from grave errors in diagnosis through the untruthful histories given by patients. In closing, he recommends the greatest care to be exercised, particularly in regard to the matter of asking questions as to the absence of menstruation. A question should be put in as casual a manner as possible as to when the last period took place; if within a month, exercise the utmost caution to prove that the case cannot be one of pregnancy. The great probability is that it is not one; but the patient may be untruthful, and even regularly recurring menstruation is not incompatible with pregnancy. If the answer given is to the effect that the last period was some months previous to the date of examination, and if the abdominal tumor is of a size which would be that of a pregnant uterus of corresponding date, the chances are infinitely in favor of pregnancy. It should also be ascertained whether menstruation was regular previous to its cessation, and if the ceasing was an abrupt one. If the latter, and the previous menstruations have been regular, the certainty of the diagnosis of pregnancy is complete. If the previous menstruations have been irregular and the cessation not sudden, the history altogether fails, and may be entirely neglected. It should be borne in mind that the adolescent anæmia of young girls suspends their menstrual flow almost invariably, but it does not necessarily interfere with their productive capacity.

The diagnosis of pregnancy is a perplexing question not only in the illegitimately pregnant woman. Even in cases where the patient gives an honest history as far as it is in her power, it is sometimes impossible to tell before the movement of the child is felt. The most careful physicians slip up once in a while on this point, sometimes in what appear to be positive cases.—*Massachusetts Med. Jour.*

Blood in the Secretion of the Mammary Gland.

At a meeting of the Society of Physicians of Warsaw, Dr. Wassilieff exhibited a woman in whom the ducts of the right mammary gland gave exit to milk mixed with

blood. The woman, 30 years of age, had been four times confined. The last accouchement was two years ago, and a year later she had weaned her babe. The flow from the breast, a mixture of blood and milk, had begun a month previously, and its daily amount could not be exactly determined. Microscopical examination revealed the presence of fat-globules, cells in a state of fatty degeneration, and more or less altered blood-corpuscles. There was nothing abnormal as regards the general health or the genital organs. The menses were regular.

Vaginal Secretions in Pregnancy.

Konig (*Amer. Jour. Obstet.*) states that he has found in the lochia the streptococcus most frequently, and but seldom the staphylococcus aureus, and never the staphylococcus albus. After considering minutely the reaction of the vaginal secretion, which in 300 pregnant women he found to be distinctly acid, he concludes that in pathological conditions the secretions attain a much higher degree of acidity, so that the streptococcus pyogenes can hardly thrive therein; at least he was unable to obtain cultures of this germ. He further concludes that the vaginal secretion of every untouched pregnant woman contains nothing pathogenic, the thrush or gonococcus germ excepted. Both are bacteria which upon the usual media of culture are aerobic at the body temperature. The vagina of every untouched pregnant patient is therefore aseptic. Vaginal injections of antiseptics are dangerous in the ordinary patient, as they may chemically lessen the resistance of the tissues to bacteria, and increase the intensity of septic endometritis by washing bacteria into the uterine cavity. —*Medical Standard.*

THERAPEUTICS.

Treatment of Diphtheria.

Weibgen (*Deut. Med. Woch.*, July 19, 1894) describes the treatment pursued in Hahn's clinic since 1880. During the past few years it has been customary to apply an ice collar, and to order hourly gargling with a 4 per cent. solution of potassic chlorate, or, if much fœtor is present, with a ½ per thousand solution of potassic permanganate. If gargling is impossible a spray is used. In nasal diphtheria the nose is syringed out with boracic acid (2 per cent.) or the above-named permanganate solution; if bleeding occurs the nostril is plugged. In mixed infections it is said that large rectal injections (boracic acid 2 per cent.) are useful. If signs of laryngeal obstruction are present on admission it has not always been found necessary to do tracheotomy, as these symptoms may subside under the use of steam. If, however, the dyspnœa is urgent, and the child weak and somnolent with retraction of the soft parts, a low tracheotomy is performed at once. Pneumonia is not a contra-indication to tracheotomy, but marked sepsis is, the dyspnœa here being often due to the infection. The cannula is removed about the fifth or sixth day. If, owing to paralysis, the food gets into the larynx, the cannula is put in again. Sometimes it has been found necessary to feed the patient with a tube. The number of recoveries has steadily increased from 46 per cent. in 1880 to 63 per cent. in 1893 among the non-tracheotomized, and from 20.5 to 40 per cent. among the tracheotomized. The earlier in the disease the child was admitted the better the prognosis. Sixty-five cases have been treated with the specific serum; of these, 72 per cent. of the non-tracheotomized and 44 per cent. of the tracheotomized recovered. The epidemic, however, was of a mild type, and the author says that similar good results have been obtained in previous years in like epidemics. A definite conclusion upon the serum treatment cannot be given until larger numbers are forthcoming, and until the treatment has been in use over longer periods of time (see *Epitome*, May 5, 1894, par 365).—*British Med. Journal.*

EAR, NOSE AND THROAT.

The Treatment of Chronic Suppurative Otitis Media.

Bacon (*New York Eye and Ear Infirmary Reports*) says the usual treatment employed in the simple, uncomplicated cases is syringing the ear with warm water once or several times a day, according to the quantity and character of the discharge, and the instillation of the following drops:

℞ Zinci sulph..... gr. ii to gr. iv.
Acid boracic..... gr. x.
Aq. destil..... ʒ i.
M.

Other drops used were those containing sulphate of copper or acetate of lead, which should be used when the discharge is not checked by sulphate of zinc.

When small granulations are present, these should be cauterized with nitrate of silver or chromic acid fused on the end of a probe, but when they are of large size or associated with caries, they should be thoroughly removed with Blake's snare or with curettes.

For small polypi or granulations the so-called alcohol treatment, consisting in the instillation of alcohol and boracic acid (20 grains to 1 fluid ounce), is very successful in some instances, while in the treatment of granulations arising from carious walls he has met with marked success in the use of alcohol and iodoform (20 grains to 1 fluid ounce). With some patients it will be necessary to dilute the alcohol one-half with water, as they otherwise complain of pain after the instillation of the drops.—*Thera. Gazette.*

GYNECOLOGY.

The Treatment of Rupture of the Uterus.

Merz (*Archiv. fur Gynakologie*) describes two cases of rupture of the uterus which came under his observation, and tabulates all the hitherto published cases, giving an analytical review of them. In fifty-four cases celiotomy was performed with 48.1 per cent. recovery. He arrives at the following conclusions:

1. If only the trunk and extremities of the fetus have escaped into the abdominal cavity, and the head lies over the pelvis, the woman should be delivered *per vias naturales*, either with the forceps or by perforation and craniotractor.

2. If the head of the fetus or the whole body has escaped into the abdominal cavity, version and extraction, as frequently advised, should not be attempted, but celiotomy should be done at once, and the fetus delivered through the abdominal incision.

3. In the latter case the rupture should be carefully sutured.

4. If the woman has been delivered *per vias naturales* and the conditions are very favorable, celiotomy and suture of the rupture should follow the birth immediately.

5. If the conditions are not favorable, then drainage with iodoform gauze without irrigation should be employed.

6. If the uterus is markedly degenerated, or if septic endometritis has developed, a Porro operation should bed one.—*University Medical Magazine.*

Ventro-Fixation of the Uterus.

After reporting some cases of ventro-fixation, Sinclair (*Medical Chronicle*) concludes a thorough paper upon this subject as follows:

1. The various published series of cases show that the element of danger is almost *nil*. The present writer's series supports this opinion.

2. The operation, efficiently performed, is a permanent cure of the troubles arising from chronic retroflexion of the uterus, complicated with adhesions or inflammatory affections of the tubes and ovaries.

3. When pregnancy occurs after the operation no distress is experienced by the patient and no unusual phenomena are observable during pregnancy, parturition or the puerperal state.

4 Contrary to what might be expected, bladder troubles are quite the exception after the operation, and these discomforts are almost certainly avoidable by care in operating.

5. In a certain proportion of the cases ventral hernia occurs at the site of the cicatrix. How this is to be prevented is one of the problems of the future.

6. After making full allowance for the element of risk and the incidental drawbacks, the operation of ventro-fixation is not only justifiable, but it is indicated in a certain class of cases of retroflexion of the uterus with complications.—*Med. Review.*

OPHTHALMOLOGY.

Affections of the Eyes in Relation to Gynecology and Obstetrics.

Ramsay, of Glasgow, states that at puberty there is an increasing frequency of inflammatory diseases of the cornea, sclerotica, iris and choroid as well as retina and optic nerve. Sharpness of vision and the field of vision is diminished two or three days before menstruation and is most marked on the third or fourth day. The sense of color, especially green, also suffers. Vicarious menstruation in the bulb often has been observed. The most important eye affection of pregnancy is the so-called albuminuric retinitis, consisting in either temporary complete blindness without any marked affection of the retina, or in characteristic lesions of the optic nerve and retina without noticeable loss of vision. The latter is more or less persistent and may in complications with uræmia cause permanent blindness. In the so-called albuminuric retinitis of pregnancy the disease may be limited to one eye, but in chronic nephritis both eyes are usually affected. Separation of the retina may occur with or without albuminuric retinitis. The prognosis is generally favorable. In the puerperal period embolism of the central retinal artery has been known to occur, also ophthalmia and atrophy of the optic nerve after severe hemorrhages. Atrophy of the nerve has been observed in the nursing period with frequent child-bearing also episcleritis in long-continued lactation and stoppage of the tear duct with formation of abscesses. The vitality of the cornea is also lowered by long-continued nursing and slight injury to it may result in protracted suppuration.—*Centralblatt fur Gynakologie.*

New Sign of Lead Poisoning.

In eighteen out of twenty persons affected with lead poisoning M. E. Destree (published in the *Journal de Medecine de Bruxelles*) has observed a narrow zone of hyperesthesia at the level of the articulation of the manubrium with the ensiform cartilage. As a general rule, pressure on the sternum is readily painful only under one or two conditions—namely, when the bone is diseased, as is the case in leucocythemia with lesions of the bone marrow, or when the thoracic wall and the skin are hyperesthetic, as happens in hysteria, sometimes in neurasthenia, and often in chronic alcoholism. But in these latter cases the hyperesthesia is not found to be so limited in extent as it is in lead poisoning. Saturnine hyperesthesia is indeed a symptom of nervous origin, comparable to the intercostal neuralgias observed by Rosenthal. "There is nothing astonishing," says the author, "in the fact that the sternal hyperesthesia is so precisely marked, when we remember that Beau has shown that there is never any anesthesia at the level of the scrobiculus cordis in lead poisoning, and that in lead colic there is very decided hyperesthesia of the abdominal wall."—*New York Med. Journal.*

A Means of Preventing Hemorrhage Consequent Upon Ablation of the Tonsils.

Dr. W. Ward states that this may be accomplished by practicing deep interstitial injections into the tonsils of the following solution:

℞	Sulphate of iron	gr. xv
	Dissolve in:	
	Distilled water	ʒijss
	Add:	
	Hydrochlorate of cocaine, 10 per cent. solution	ʒijss

F. S. A.—For external use.

From thirty to sixty minims of this solution are injected into each tonsil, after which, it is said, scarcely any hemorrhage follows extirpation of the glands.

BACTERIOLOGY.

The Transmission of Bacilli Through the Placenta

from the mother to the fetus is a question which has invoked considerable interesting discussion among pathologists since the causation of disease by micro-organisms has been definitely settled, for hereupon rests the explanation of many of the apparently hereditary diseases. I say apparently hereditary advisedly, for but few would be willing to assert that any of the known micro-organisms are transmitted in a true hereditary manner either through and within the spermatozogoon from the male parent or through and within the ova of the female. This and this only can be true heredity; all received after their junction must in the natural order of development be acquired.

During the earlier investigations on this subject the placenta was believed to present an impenetrable barrier to the progress of micro-organisms toward the fetus, and various theories were advanced to explain the apparent discrepancies; but more recent experiments, especially those of Malvoz and Juequet, have shown that when injuries have been received by the placenta the point of injury may form a point or open door by which pathogenic organisms may gain entry to the fetal organism and there commit their ravages.

The frequency with which the placenta receives injuries can be verified by any obstetrician by a careful examination of placentæ as they are received in his practice, and one would wonder that more cases of apparent heredity do not occur; but rarely indeed can you find an infant that shows unmistakable evidence of tuberculosis, especially at birth. While the books contain vague references to tubercular fetus, we find but one instance recorded in which a systematic examination was made. In this case bacilli were found in the placenta, but not in such positions as to indicate that they had been received from the mother, leaving the question resting upon the experiments above referred to, making true heredity extremely improbable, apparently possible, but rare.—H. C. F., *Columbus Med. Journal.*

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FOUR WEEKS ENDING SEPTEMBER 22, 1894.

Fessenden, C. S. D., Surgeon. Granted leave of absence for thirty days, September 12th, 1894.

Murray, R. D., Surgeon. To proceed to Beaufort, S. C., on special duty, September 20th, 1894.

Bailhache, P. H., Surgeon. Detailed to represent service at meeting of American Public Health Association, September 21st, 1894.

Vansant, John, Surgeon. Granted leave of absence for thirty days, August 30th, 1894.

Hutton, W. H. H., Surgeon. Relieved from Quarantine Inspection duty, and ordered to rejoin station, Detroit, Mich., September 12th, 1894. Granted leave of absence for thirty days, September 20th, 1894.

Sawtelle, H. W., Surgeon. Granted leave of absence for five days, September 14th, 1894.

Gassaway, J. M., Surgeon. Granted leave of absence for one day, September 17th, 1894.

Banks, C. E., Passed Assistant Surgeon. To report at Bureau for temporary duty, September 10th, 1894. Detailed to represent the service at meeting of American Public Health Association, September 21st, 1894. Relieved from temporary duty at Bureau, and directed to rejoin station (Portland, Maine), September 22d, 1894.

PROPHYLAXIS IN CHURCHES NEEDED BY THE ADOPTION OF INDIVIDUAL COMMUNION CHALICES OR CUPS.*

HOWARD S. ANDERS, A.M., M.D.,† Philadelphia.

It may seem like an invasion of the sacredness of religion for sanitary science to prescribe and recommend certain modifications in the administration of a church ordinance which has had the sanction of general usage for centuries among most intelligent Christian congregations and their pastors. Be this as it may, it is not for sanitarians to leave a stone unturned in their quest for facts and principles, for ways and means by which humanity may be led to suffer less from disease and live healthier, stronger, happier and longer. This applies intrinsically to the welfare of those cherished by and cherishing the higher, spiritual life as well as the secular.

Seemingly an unwarranted intrusion, the change urged in this paper is, nevertheless, actually an innovation; and more, it is—as I hope to prove—a sanitary improvement of a sublime Christian ordinance, and not a sacrilegious, though scientific, proposition. When it is recollected that more than ten millions of people of a nominally Christian nation signify their faith many times a year by participating in a service at once beautiful, solemn, symbolic, but, by reason of certain hazardous conditions in its practice, unhygienic, too, the scope and magnitude of this topic may readily be conceived. It is rather remarkable that the possible and occasionally probable transmission of disease by the use of the communion chalice has not been ventilated publicly until quite recently. (You all know the trite observation regarding the late apprehension of the simplest facts.) But the pace has been set, and the wholesome movement is spreading throughout the United States with rapid strides.

According to its present status, my theme divides itself naturally into three parts—namely, the historical, the rational or explanatory, the practical and suggestive.

1. Historical.—It is not unlikely that the use of individual communion cups for the wine dates back to the time when Christ himself instituted the communion for his disciples and subsequent followers. The Oriental drinking customs at that era were likewise unwittingly hygienic in this respect. These statements are in accord with some of the best biblical historians, exegetists, and critics, and I have been assured by several learned and progressive divines that there is absolutely no scriptural objection whatever to a reversion to the individual communion chalices, particularly as cleanliness (which is next to Godliness) and the conservation of health

*Read before the Philadelphia County Medical Society September 26, 1894.

†Lecturer and Clinical Instructor on Physical Diagnosis, Medico-Chirurgical College, and Physician to the Samaritan Hospital, Philadelphia.

would thus be promoted. I may refer here to the classic painting of "The Lord's Supper," by Da Vinci, who represents each disciple with his own cup. How long or to what extent this ordinance was practiced as instituted it is difficult to say and irrelevant to the purpose and province of this paper. Suffice it to note that in most Protestant churches of to-day the habit at a communion service is for the communicants to partake of the wine from but one or several chalices respectively. Since it often happens that hundreds of persons receive the wine from the same cup, and since the virus of certain infectious diseases may be present in the oral secretions of some, their transference to others by this contact at the rim of the cup is quite possible.

This is the condition which faces the sanitarian, the problem which calls for solution. Fortunately, the latter is easy, and its results reasonably efficacious. The questions which offer themselves embrace several aspects in connection with the anticipated prophylaxis, and may be expressed as follows: Is there a real danger of the transmission of disease from mouth to mouth in the observance of communion by the use of a common cup or cups? If so, what diseases, and of what gravity are they? Have any cases of sickness thus arisen? Would an individual-cup system obviate these dangers? Would its adoption detract from the impressiveness of the spiritual intent of the service? In short, is it at once practicable and practical?

If one may be permitted to estimate rightly the decision of recent events, the above questions are now virtually answered by several churches and hundreds of worshipers. Though the actual substitution of what has been fitly termed the individual communion cup for the common one is only in its inception, the appreciation of the idea is more advanced, as recent newspaper agitation shows.

But to Dr. Chas. Forbes,* of Rochester, N. Y., we are indebted for having first investigated scientifically the dangers lurking in the communion chalice, detected them, and then designed suitable means of obviating them. His report to the Rochester Pathological Society was adopted, with resolutions recommending most strongly to the various churches the modification to the individual cups.

This brings us, then, to the fundamental argument for the proposed change.

2. RATIONAL.—(*a*) *Reasoning by induction,* the inference is logical that if certain microbes are discovered in the wine taken from a common chalice used at communion, and those microbes are known to be pathogenic, then such wine so used is a menace to the health of the participants, provided, of course, that the wine was uncontaminated before it was passed to the members. Evidence, both bacteriological and clinical, is not wanting to verify the premises.

Dr. Forbes found in the dregs of a common cup contamination from two sources, viz., the mouth and clothing. From the former epithelial cells, bacillar spores and various bacteria, and mucus; from the latter, fibrous material. Control experiments showed the unused wine to be practically sterile. He referred, also, as illustration by analogy, to an epidemic of diphtheria which occurred recently among twenty-four families of Rochester, and the origin of which was traced clearly to a common drinking-cup which all of the sick had used. The bacilli of Loeffler were found in great numbers in the wipings from the cup's rim. Again, a fatal epidemic of the same disease in San José, Cal., was traced to a common communion chalice contaminated by a man sick with the malady in its early stage.

About June 1st of the present year, in the laboratory of the Medico-Chirurgical Hospital, I completed, with the kind aid of Dr. C. L. Furbush, a bacteriologic examination of the dregs from an ordinary communion chalice used by many communicants at a service in the Fourth Baptist Church of this city. Five slides were prepared from agar-agar cultures, the specimens stained after the Ziehl-Neilson method, and in two preparations several tubercle bacilli were found. Other preparations made from sterile bouillon media revealed the pus staphylococci. Microscopical examination of the dregs direct showed numerous pus-cells and an abundance of pavement epithelium, along with the ovoid, purplish cells of the grape. *Verbum sapienti sat.* "A word to the wise is sufficient."

But if this is one instance, may there not have been hundreds in the course of

*Passed Assistant Sanitary Inspector U. S. Marine Hospital Service, Health Officer of the Port of Genesee, N. Y.

time when health and life have been jeopardized, interrupted and sacrificed in apparently inexplicable fashion? Innocently and religiously may have been these sacrifices in the past—in the black background of the historical panorama where stalked with prevailing tread the figures of cruel fanaticism, bigotry, ignorance and superstition. But is it religious heroism to suffer needlessly the martyrdom of bacillar attacks while we are strong in prophylactic defense as well as able in knowledge? I ask, is it reasonable, is it safe, is it right or God-forbidden to continue the administration of an ordinance which exposes so many to the possibilities of infection? Furthermore, while it is manifestly difficult to prove the origin of many cases of sickness from a common communion chalice, and while positive proof of but one case would be sufficient reason for systematic prophylaxis and the use of the individual chalice, yet even this is *unnecessary* to justify the change in the light of our present knowledge.

(*b*) *Reasoning by Deduction.* The second part of the argument is then naturally in order, and need not be elaborate. That there are certain underlying principles of hygiene applicable to this subject and all-sufficient for the result desired, namely, the prevention of transmission of disease through the medium of a common chalice, you are all well aware. Cogent reasons for prophylaxis in churches regarding this ordinance may be deduced by analogy.

Truth is truth everywhere, whether in the natural or spiritual world. It is stable, harmonious. The truths of hygiene are of incomparable value to the welfare of all; he who heeds them not suffers, and soon is not. There are many truths yet to be discovered and applied, and many just growing into recognition and pleading for utilization for humanity's sake. The latter embraces this need of prophylaxis in the use of a common communion cup.

We do know that certain pathogenic microörganisms and their corresponding viruses or ptomaïnes are communicable and inoculable, from mouth to mouth, by direct contact, or intermediate, as with a common drinking vessel; that the various habits of life and customs of society, laxity in prudence and precaution, and what-not, are insidious auxiliaries in the matter of infection; and that the practice of sanitary principles erects a hidden but potent barrier between the besieging microphytes and man, the besieged. The true spirit in churches cannot but lead it to adjust itself in the observance of a sacred ordinance so that a helpful truth of hygiene shall not be violated, but contribute indirectly to the good being wrought for the higher nature of man, by keeping the mind sound in a *sound body*. Indeed, it would seem to be wrong and unchristian not to make use of knowledge which in any way aids in preventing or alleviating human suffering.

The fundamental principle in this movement, then, is the prevention of disease and that for which we should contend most earnestly: a principle of medical science as fundamental as the "*Cogito, ergo sum*" of the philosophers, or as the faith of perfect trust and obedience of one of God's true worshipers.

That the preventability of a contagious disease is a fact, is as obvious as is that of its contagiousness. While the more contagious diseases are becoming less prevalent on account of the alarm which leads to more intelligent, stringent and cooperative measures of private and public quarantine, there is great danger, however, that the less communicable affections may be dealt with too lightly, because of the practical neglect of the common, every-day modes of transmission. It is on this account, probably, that such diseases as tuberculosis and typhoid fever are so prevalent, and that they swell the mortality-rate so much. Besides the two diseases mentioned, among others which may be placed in the category of communicability from the sick to the well through the medium of a general communion chalice are the following: Syphilis, diphtheria and croup, scarlatina, whooping-cough, follicular tonsillitis, perhaps measles and pneumonia. Dentists urge strongly the necessity of avoiding a common cup, and thereby possible infection from alveolar abscesses, diseased gums and the nasty malady known as "Rigg's disease," or *pyorrhea alveolaris*.

Who will say that perhaps many an innocent person has not acquired disease from a common communion chalice, or that the dangers residing in its use are sensational and imaginary, and not real, grave and well-nigh universal in Christian communities? Is it not clearly "illogical to pass a cup from mouth to mouth in a religious ceremony when the same practice

is justly condemned in our homes and in other public assemblages?"

From little less than axiomatic sanitary principles, then, the deduction is made that the substitution of individual, separate cups is urgently needed. These can be kept clean and free from the possible disease contamination by the innocent or careless. They are sanitary, safe, practicable, and moreover, as before intimated, they have the sanction of scriptural precedent, therefore not justly provocative of irreverence or lack of dignity, solemn impressiveness or deep devotion.

3. PRACTICAL AND SUGGESTIVE.—Lastly, would the adoption of an individual-cup system be practical as well as practicable? Recent experience answers this question in the affirmative. The adoption of anything which releases man from the dangers of disease is practicable; the progress of time, development of ingenuity, and an enterprising, persistent industriousness combine to look after its practical accomplishment.

If there were thirteen cups at the Lord's Supper, why should there not be two hundred, or five hundred, or one thousand for the needs of any congregation? The communion ordinance as administered in the Rochester churches by individual cups is entirely satisfactory, and the wonder is expressed that the change was not effected before. The celebration of the service is expedited, is conducted with a unity and harmony of action and impressiveness of spirit at once beautiful and elevating. I may state that between services the cups are sterilized in wire baskets and kept in tight closets, on rack or tray formed holders provided with lids to exclude any dust.

Philadelphia arrogates to herself the honor of being the medical center of the United States, and justly too, I think—with all deference to other cities. It behooves us, therefore, as the representative medical society of Philadelphia, to take a front place in furthering a sanitary movement which is bound to go forward with an increased impetus of beneficence by reason of its sanction and recommendation of this individual-chalice method of administering the communion ceremony in all the various churches now using the common chalices. Prompt action to that end will, I am sure, be termed by all but an unfit minority a worthy and lofty expression of science and sympathy conjoined.

Public attention and interest will also be aroused more energetically and widely; and after intelligent, unbiased and dispassionate consideration, individual chalices will be adopted throughout the country with proportionate readiness; and with their adoption into practice another modest quotum may be added to our hopes and efforts in attaining a high standard of public health and an ever-increasing longevity.

WHEREAS, The present use of common communion chalices or cups in churches exposes the communicants to the positive danger of acquiring certain contagious diseases, and is therefore a menace to the public health; be it

***Resolved,* That the Philadelphia County Medical Society hereby recommends the adoption of an individual-cup method or system of administering the communion wine in all churches, of whatever denomination or sect, where the common communion cup is now in use; and**

***Resolved,* That this society believes from undoubted evidence that an individual chalice or cup system would be a clean and safe and reliable means of preventing the liability to the spread of contagious disease from such a source as may reside in the ordinary chalice.**

The Absorption of Odors by Milk.

Parville relates some interesting facts upon this subject. If a can of milk is placed near an open vessel containing turpentine, the smell of turpentine is soon communicated to the milk. The same result occurs as regards tobacco, paraffin, asafetida, camphor, and many other strong-smelling substances. Milk should also be kept at a distance from every volatile substance, and milk which has stood in sick-chambers should never be drunk. The power of milk to disguise the taste of drugs—as potassium iodide, opium, salicylate, etc.—is well known.—*Gaillard's Med. Jour.*

Diet in Pneumonia.

The following rules (*N. E. Med. Gaz.*) may be laid down as to feeding pneumonia patients: 1. Give no solid food. 2. Let the food be simple and nutritious. 3. Give food at frequent intervals and in small quantities. 4. Let the patient have all the pure cold water and cooling drinks he may desire. 5. Solid food, given during convalescence, will often cause a relapse.

A CASE OF PANHYSTERECTOMY—RECOVERY.*

MARK A. RODGERS, M.D., PITTSBURG, PA.

Miss McC., aged 44, unmarried and a virgin. The patient presented a history of 18 years suffering from the various uterine syndroma. For six weeks prior to the time I first saw her she had been bedfast. She was rapidly declining in health and strength, and it was evident that unless she received immediate relief the termination would be early death from exhaustion.

The case was referred to me by Dr. George H. Miller, of MacDonald, Pa., and with him I first saw the case in consultation on September 1, 1894. I found the patient weak and emaciated, with a rapid, feeble pulse and, as stated above, in a very depraved state of general health. On bimanual examination I discovered a mural fibroid about the size of a cocoanut, involving the anterior uterine wall; and I could locate several smaller fibroids in various positions, intramural, mural and extramural. As the uterus was freely movable I advised immediate hysterectomy, and on September 3d the patient entered my private hospital. On September 5th I operated.

It had been my intention to remove the uterus if possible through the vagina, but after anesthetization when the patient was placed on the table, I discovered that the vagina was so exceedingly small that it would be impossible to deliver it by that route without such formidable incisions and the application of so much force that I concluded that it were foolish to attempt it. I reflected that to open the abdomen did not materially enhance the danger of the operation. Consequently, the patient was placed in the Trendelenberg posture, and the abdomen opened from the umbilicus to within an inch and a half of the pubis. The broad ligaments were then ligated with silk on either side down to the vagina, the bladder dissected from the uterus, clamps placed on the broad ligaments between the ligatures and the uterus, and the whole mass, including the cervix, ovaries and tubes, ablated. The vagina was next lightly packed with iodoform gauze. Then with a continuous catgut suture, the peritoneum was closed over the stumps of the broad ligaments, the posterior vaginal wall attached to the fundus of the bladder, and the abdomen closed.

The only interesting feature of the operation consisted in the manner in which the peritoneum was approximated. From the peritoneum on the posterior wall of the vagina to the peritoneum on the fundus of the bladder seems like a rather long distance to bring tissues for approximation, but it is done easily and without inconvenience or ill-effect. That portion of the bladder which had been attached to the uterus and which therefore presented a raw surface, together with the cut ends of the vagina, were inverted into the vaginal cavity and were maintained in that position by the catgut suture; so that when the operation was completed there was not a vestige of raw surface to be seen within the pelvis.

The patient made a rapid recovery, leaving the hospital for her home sixteen days after the operation.

The present tendency to operate through the vagina should not, I think, be carried to extremes. Personally, I prefer to open the abdomen in every case where it is necessary to incise the vaginal walls or do episiotomy or perineal section. For I believe there is less danger in an abdominal incision than in lacerations or extensive incisions in the vagina; and even those of the most indifferent surgical experience are aware of the tendency toward suppuration in tissues which have been subjected to traction.

Marcellment, so strenuously advocated by Péan, is only applicable in the rarest cases. As was pointed out by Martin at the recent congress in Rome, the possible dangers from ruptured pus collections, concealed hemorrhage and all the various complications which may arise from operating in an obscured field, more than counteract any advantage which might be derived from adhering to this method.

*Reported to the Pittsburg Academy of Medicine, September 24, 1894.

COMMUNICATIONS.

REPORT OF A GROUP OF CASES COVERING ALMOST THE ENTIRE FIELD OF ABDOMINAL SURGERY.*

M. PRICE, M.D., PHILADELPHIA.

CASE I.—Miss McC., a patient of Dr. Henry Lehman, suffering from a large multilocular tumor of the right side which had been noticed for several years, but gave no trouble. All at once it developed very rapidly, with symptoms of peritonitis and every indication of twisted pedicle. She was sent into the hospital, and the operation done at once. The tumor was a large, intensely black-looking mass adhering to the entire abdominal viscera, but the adhesions were easily broken, the tumor emptied and removed. The pedicle was found to be twisted four times. Rapid and uninterrupted recovery.

CASE II.—Mrs. M. J., a patient of Dr. George L. Romine, Lambertville, Pa., suffering from nodular fibroid of the uterus of five years' standing. Suffering from marked nervous excitement and depression alternately. Mental symptoms very marked. Operation—removal of both sides. Rapid recovery, with disappearance of all physical and nervous symptoms.

CASE III.—Miss L. P., a patient of Dr. Murphy. This patient had been suffering for a long time with pelvic disease; had been treated by a number of practitioners. None seemed to discover her trouble until Dr. Murphy carefully examined her case and suspected extra-uterine pregnancy. She asked me to see the case and confirm her diagnosis. I did so, and she was sent into the hospital for operation. The right side was an old and capsulated extra-uterine pregnancy and clot. The removal of the specimen, sac and blood; irrigation, glass drainage and rapid recovery.

CASE IV.—Miss D., eighteen years of age, a patient of Dr. Rush Leaman. This patient has been suffering from chronic gonorrhœa for a year. She was beautiful, but uncontrollable morally; had one miscarriage. Dr. Leaman asked me to see the case after the girl had been suffering a number of weeks with peritonitis. The doctor had been called a few days previous, and stated to me that she was suffering from gonorrhœal pelvic disease. My examination confirmed his opinion; also his recommendation that an operation was the only thing that would relieve her. She was taken to the hospital and both sides removed. When brought outside the abdomen, ugly irritated gonorrhœal pus poured from the fimbriated extremity of both tubes. The peritoneum was thoroughly irrigated; glass drainage twenty-four hours. When she left the hospital, four weeks afterward, she was in perfect health. After the operation she stated that at no time since had she suffered as she did weeks before the operation.

CASE V.—Mrs. S. S., suffering from trouble in the right side in the region of the appendix; unable to walk without supporting that side. When walking stooped toward the right side. Had been ailing five years, and for three months before the operation was a confirmed invalid. Appendicitis was suspected. There was great tenderness over the appendix, but no induration or tumor that could be discovered. She was opened in the median line, and the right tube and the vermiform appendix were found glued together, with an abscess of the tube and also one of the appendix. The vermiform appendix was carefully tied off, the diseased uterine appendage also removed, and the patient made a rapid recovery, with the entire removal of all symptoms.

CASE VI.—Mrs. R., thirty-four years of age, a patient of Dr. Clara Dercum. This is an exceedingly interesting case because there seemed to be some doubt as to the diagnosis of her trouble. Several good practitioners carefully examined her, and wavered between mutilocular cyst and pregnancy. Twice they went to the house to operate, but decided to wait, owing to the inability to say just what the trouble was. She fell into the hands of Dr. Der-

*Read before Philadelphia County Medical Society September 12, 1894.

cum, and she at once decided it was a mutilocular cyst. I was asked to see the patient to operate. I did so with the assistance of Dr. Dercum, Dr. Joseph Price, and Dr. George Hughes. I found the tumor to be a mutilocular cyst of the right side, weighing about thirty-five pounds. She made an uninterrupted recovery. Operation in the hospital.

CASE VII.—Mrs. L., twenty-six years of age; two children; suffering from double ovarian and tubal disease. This woman has been delivered by me twice, of fine boys. After her first confinement she was badly diseased by her husband after his regiment returned from camp. It was very hard to get her to continue the treatment sufficiently long for her to get perfectly well. The vaginal discharge continued until the second boy's birth. There were no symptoms of ovarian or tubal disease at that time, but I thought it doubtful that she would ever become pregnant after her first delivery. She conceived and went to term notwithstanding. I took all precautions during its delivery, and of the child's eyes immediately after the delivery. The baby had an angry purulent ophthalmia. The mother seemed to make a satisfactory recovery, but was again infected by her husband five weeks after the delivery, and continued to do badly, having repeated attacks of pelvic inflammation, which would get better but not well. After a year and a half of chronic invalidism she had well-marked disease on both sides. I had her taken to the hospital, and both sides removed for pus tubes and ovarian abscess on one side; glass drainage. She made a most satisfactory recovery.

CASE VIII.—Mrs. F. S., Trenton, N. J., a patient of Dr. Joseph Shaw, a colored woman, aged eighteen years, married, no children. Apparently in perfect health up to three months prior to the operation. She then began to rapidly enlarge and suffer from pressure symptoms. I carefully examined the patient with Dr. Shaw, and we decided that it was a fibroid undergoing malignant changes. She was at once sent to the hospital and the entire tumor and womb extirpated. She made a rapid and uninterrupted recovery.

CASE IX.—Mrs. C., Trenton, N. J., a patient of Dr. Joseph Shaw; large ovarian tumor, which had been mistaken for pregnancy by two good men, when Dr. Shaw was called in to treat the case. He decided it was ovarian disease, and asked me to see her in consultation. We had no trouble in coming to a conclusion that it was a multilocular tumor. The patient had been previously prepared for operation by Dr. Shaw, and with his assistance and that of Dr. Hughes I at once removed the tumor. She made a rapid and uninterrupted recovery.

CASE X.—William H. H. S., eleven years old, a patient of Dr. Hollingshead, Pemberton, N. J., was taken July 25th with pain in the right iliac fossa. He was freely purged, but without any benefit. On the first day of August there was free discharge of pus from the bowel; this relieved him temporarily. On August 3d he was seized with very severe pain on the right side. This continued to increase in severity, and I was telegraphed for. I found the boy suffering with severe pain on the right side, with an indurated mass extending from a little below the crest of the ilium to the region of the right kidney. An incision an inch and a half long was made over the most prominent point of the induration; a quantity of pus was discharged; pus also discharged from the bowel. The head of the colon was full of small openings. Thorough breaking up of adhesions in the pus cavity, which seemed to be sacculated; thorough irrigation and gauze and rubber drainage. This was removed on the second day, and light gauze packing used for several days longer, and the wound allowed to granulate from the bottom.

This is the fourth case of appendicitis operated on for Dr. Hollingshead within the last two years, two of the four having fecal fistula, which healed in from five to six days. All the cases were within a radius of a mile, and all recovered.

CASE XI.—Mrs. Rebecca V. S., thirty-two years of age, a patient of Dr. Hollingshead, Pemberton, N. J. Mrs. S. has been an invalid for two or three months, suffering from pain on the right side. She was completely incapacitated for work for about three weeks. She is the mother of the boy just reported, who was operated on for appendicitis. They were both in the same bed, the boy too ill to be removed, and he was operated on at once. The mother was removed to Dr. Joseph Price's private hospital, and was there operated on by me. She was suffering from a right

TABLE OF OPERATIONS FROM MAY, 1893, TO APRIL, 1894.

Date.	Name.	Age.	Children	Miscar'ge	Pathological condition.	Operation.	Result.
March 27	Mrs. W.,* patient of Dr. McLaine, Dr. Matlack, Philadelphia.	43	2	2	Multinodular fibroid umbilical hernia.	Complete extirpation.	Died March 27.
March 29	Mrs. P., patient of Dr. E. M. Harvey, Media, Pa.	38	0	2	Multinodular fibroid pelvis bound, surrounded by strong bands of adhesions.	Supra-vaginal extra-peritoneal hysterectomy.	Recovery.
April 8	Mrs. C., patient of Dr. J. J. Owen, Philadelphia.	50	7	0	Intra-uterine cancer.	Complete extirpation.	Recovery.
April 8	Miss C., Philadelphia.	42	.	..	Large multinodular fibroid, omental, large and small bowel adherent, general and strong.	Tumor deperitonized and nodules enucleated; complete extirpation, irrigation, and drainage.	Recovery.

* The patient was dying from obstruction of the bowel from pressure of the tumor on the transverse colon, which passed under the tumor; obstruction also in an incarcerated umbilical hernia. Defecation and the passage of flatus was impossible. She had stercoraceous vomiting for some forty-eight hours, and was evidently dying at the time of the operation, from which she never reacted. The operation was done to remove pressure and favor the escape of gas.

tubal abscess, which had ruptured, producing local peritonitis and infection of the pelvis, with abscess. Both sides had to be removed, and an abscess sac enucleated. Free irrigation, glass drainage. A great number of bowel adhesions in this case had to be broken, some stitching of the bowel necessary. The patient made an uninterrupted recovery.

CASE XII.—Dr. F. H., of Columbia, Pa., was operated on August 9th for an abscess on the right side, underneath the ribs. Its capsule was attached anteriorly to the abdominal wall and peritoneum; posterior between the liver and the peritoneum. An inflammatory diaphragm only. The abscess contained only probably half a pint of pus, and pushed against the diaphragm, giving him severe hiccough and spasmodic cough. It originated two years ago, from a fall on his door-step. His ribs were supposed to have been broken, and he was seen by Dr. J. W. White, of this city, and strapped, which gave great relief at the time. He was afterward seen by Dr. W. W. Keen, who advised him as to his case. I saw him about six weeks before the operation and advised him to have the trouble removed. He said he would as soon as he could, and on the 9th of August, in this city, I operated, irrigated and drained the pus cavity. He made a rapid recovery. The feature in this case to which I wish to call your attention, is the fact that it was two years in developing. The pus was perfectly sweet and bland. At the time of the operation he was broken down from pain and cough.

CASE XIII.—Mrs. R., a patient of Dr. Eckman, twenty-eight years of age; three children; confined to bed for three months with symptoms of tuberculosis—only a very slight cough. After a very careful examination of the sputa, no tubercle bacilli could be detected; a careful pelvic examination showed well-marked pelvic inflammatory disease, womb fixed, and exceedingly tender masses on either side. Her temperature was never normal; she had daily chills; abdomen tender, with a history of puerperal peritonitis thirteen months previous.

The absence of positive proof of general tuberculosis and the presence of sufficient pelvic trouble to account for her symptoms, warranted us in operating for her relief. There were no symptoms of dropsy.

The patient was operated on, and tuberculosis of the peritoneum, with all the viscera matted together and covered with tubercles, was found to be the cause.

All the adhesions were separated and the bowels, omentum and mesentery dusted with iodoform. The operation did not make any change in her so far as we could see, either for better or worse; she lingered until the eighth day, and then died. Post mortem was made by Dr. Eckman, and general tuberculosis was found to be the cause of death.

There is one question that suggests itself in this case: Why was there no dropsy? Did its absence indicate general infection? I have seen many cases as bad as this, accompanied with dropsy, that the opening and iodoform treatment seemed to cure. In my knowledge, none of them show any symptoms to-day of tuberculosis

WHEN IS THE ADMINISTRATION OF THE SULPHATE OF STRYCHNINE CONTRA-INDICATED DURING GESTATION?*

T. RIDGWAY BARKER, M.D., PHILADELPHIA.

In presenting this subject for consideration and discussion this evening, it is not my purpose to depreciate or undervalue the great benefit the sulphate of strychnine is capable of rendering in a majority of the cases of pregnancy.

The claims made for it by my friend, Dr. Duff, of Pittsburg, who has devoted himself with much enthusiasm to the study of this drug in its relation to obstetric practice, are not, I think, without justification; but, with the estimable conservatism of a seeker after scientific truth, he leaves the subject open for further study and research, awaiting until time and a wider experience shall prove its merits.

In a paper read before the South Side Medical Society of Pittsburg, and in one presented to the American Association of Obstetricians and Gynecologists, in 1893, he gives his clinical experience.

At the forty-fifth annual meeting of the American Medical Association, recently held at San Francisco, he again calls the attention of the profession to the value of strychnine, and points out that it renders abortions and premature deliveries less frequent by giving tone to the uterine muscles and nerves, as well as by its general tonic influence.

These statements are beyond question correct in the vast majority of instances; but he who would avoid error and misfortune must bear in mind that every rule has its exception, and that the latter, though often overlooked, is no whit less important than the former.

The sulphate of strychnine I have given to a score or more of women during gestation with the happiest results, and so general was the improvement in their condition that I began to think that there was no exception to this rule. I was not long left in doubt, for, as the following case reported will show, I met the exception in a most unexpected but none the less pronounced form.

Mrs. G., primipara, aged twenty-nine years; white; general health good. Last menstruated in October; previously regular. Suffered greatly from morning sickness and distressing nausea for nearly four months, which was uninfluenced by internal medication. There was besides these symptoms, costiveness and a more or less irritable bladder. The appetite was poor, and loss of flesh was quite marked as the pregnancy advanced.

In the early part of the sixth month she first complained of a sense of weight felt in the abdomen and pelvis; this was soon aggravated by soreness and pain which persisted throughout the day and night. The nervous depression in this case was all out of proportion to the severity of the symptoms, and seemed to trouble the patient more than almost anything else.

There was no kidney trouble of any kind nor evidence of swelling of limbs or face. The heart was normal save a slight anæmic murmur.

The blood was deficient in red blood cells and showed a condition typical of that found associated with pregnancy. The woman, when married, weighed some one hundred and thirty pounds, but now was much emaciated. The vagina and cervix were normal and the uterus in good position; there were no adhesions.

To judge from the size of the abdomen and the activity of the fœtus, development was progressing favorably. There existed, however, double ovarian tenderness, which denoted congestion of a pronounced type, and to this I ascribed in part the great mental depression, though, of course, much depended upon the anæmic blood supplied to the nerve centers.

Deeming this case one suitable for the administration of sulphate of strychnine from a careful analysis of the above objective and subjective symptoms, I determined to place the woman upon one-twentieth of a grain, twice a day, with the hope that it would stimulate a healthy nerve action and relieve, as has been claimed, the uterine irritability which threatened to result in an abortion.

I reasoned that the nervous disturbance was due to anæmia of the central nervous

*Read before Philadelphia County Medical Society September 12, 1894.

ganglia and involved the sympathetic system as well. That the uterus threatened to expel its contents because the nerves controlling its muscular coats were in a state of hyperæsthesia dependent upon insufficient nutrition. With this idea I placed my patient upon the drug, which experience had proved to be the best suited to overcome just such a condition as I found present.

With what result? Within thirty-six hours the uterus became more rebellious; its muscular contractions increased rather than lessened in violence, and recurred with greater frequency. The dull pain which had persisted for several days now became acute and intermittent, and radiated from the umbilicus to the loins.

An abortion was undoubtedly threatened, and might almost be considered inevitable. The sulphate of strychnine was promptly discontinued, as it had undoubtedly only made matters worse, causing a passive uterine contraction to become active, and thus augmenting the expulsive uterine forces.

A sedative mixture containing morphine, chloral, and bromide of soda in solution, was ordered to be taken every hour and the patient put to bed and directed to keep perfectly quiet. In a few hours the pains were allayed and the uterine contractions became feebler and recurred at longer intervals. These signs gave rise to a hope that the patient might yet escape an abortion.

Twenty-four hours elapsed with no return of the contractions. The prospect seemed to brighten, but only to give place within another twelve hours to a sudden and aggravated attack of pain, followed by strong uterine contractions, which, acting upon the cervix, soon overcame its constricting fibers, and an abortion was the result. In a few hours the whole uterine contents were expelled, much to the regret and disappointment of both physician and patient.

Thus ended one case of gestation in which strychnine may be said to have been the exciting cause of the abortion. Here we have what Duff probably refers to when he remarks in his paper, "I am not unmindful of the fact that I have seen apparent evil results from its administration in a few cases."

In looking over the history of the case reported, one cannot fail to be impressed with the fact that here was an instance where, had one known the exception to the rule, he would not have given strychnine, since clearly it was contra-indicated.

Instead of its acting as a sedative to the hyperæsthetic nerves through its tonic influence, it played the rôle of an excitant, and thus brought about the very result most to be deplored, namely, an abortion.

Some may take exception to the size of the dose (one-twentieth of a grain) twice a day; this I grant is not a small dose, but at the same time it is one I have frequently given with the best results, and I have found that a much smaller dose fails to be beneficial.

I do not, therefore, think that the amount administered made any material difference. That strychnine requires to be given during gestation with much more care than has heretofore been exercised, I think is very evident. Moreover, when there exists great mental depression associated with symptoms of distress and pain, referable to the pelvic region, with involvement of the uterus, I think the administration of strychnine is contra-indicated, for under such conditions it is more than likely it will act as an irritant and not as a sedative, and so will tend to produce an abortion, the very danger one is struggling to avoid.

Strychnine, then, it would appear, is indicated in cases of gestation which require a powerful nerve tonic, but contra-indicated when such cases are complicated by pronounced pelvic disorders of a nervous type.

Postal Transmission of Small-Pox.

Dr. Karkeek, the health officer of Torquay, England, records in his report for last year the occurrence of two cases of small-pox in which the infection was conveyed by correspondence from a nurse in a small-pox hospital. One of the cases occurred ten years back, and the other last April, the patient falling ill two days after leaving Torquay. His friends had suggested risk from reception of letters written by a hospital nurse engaged in attending small-pox cases, but he had pinned his faith on supposed disinfection of all letters. How far he was mistaken in his supposition was shown by the sequel.—*Med. Record.*

HYSTERIC APOPLEXY—THE DIFFICULTIES OF DIFFERENTIAL DIAGNOSIS BETWEEN THIS FORM AND CEREBRAL HEMIPLEGIA.*

DR. RENDU, PARIS, FRANCE.

The case which I am about to relate is particularly interesting on account of the apparently characteristic symptoms indicating a material lesion of the nervous system, yet this diagnosis, as you will soon perceive, is quite doubtful.

The patient is a man of sixty-one years and a road laborer, who entered the hospital last June for treatment of a recent affection of the nervous system. On the 3d of June, while at his work, he was suddenly seized with vertigo and fell upon his back, losing consciousness for a short time. He was carried home, where he returned to consciousness soon after. The next day his intellect was clear, while only headache and impossibility of working remained. That evening he expectorated a little blood, had a slight fever, general malaise, and, the day after, a pain in his left side.

His symptoms remained unchanged until the 8th of June, when he entered the hospital. He was noted as a well-developed, strong and vigorous individual, with his hair turning but slightly gray. He had no dyspnœa, yet he especially complained of functional thoracic symptoms. On the left side of his chest he suffered from a diffuse and vague pain, situated in the last four intercostal spaces. It was not spontaneous, but manifested itself on effort at deep inspiration; besides, percussion and palpation revealed a very characteristic and distinct zone of cutaneous hyperesthesia. These symptoms, with the history of hemoptysis, led to a physical examination of his chest, but the results were entirely negative. There was neither pleurisy nor pneumonia, and an intercostal neuralgia could not be diagnosticated as there were no painful and circumscribed points, but, on the contrary, a diffuse and badly outlined oversensitiveness of a large portion of the thorax. Examination of the circulatory apparatus only discovered a slight degree of atheroma, doubtless due to his age and which was characterized by a hardness of the pulse and an accentuation of the second heart sound.

Thus in spite of the history of hemoptysis and these functional disturbances, no sign of a pulmonary or cardiac lesion could be discovered. On the contrary, the nervous system seemed especially affected with intense headache, either in the frontal or occipital region. No painful neuralgic points; the predominant symptom being a persistent sensation of heaviness in the brain, dullness and dislike for work, without any somnolence. His vision was slightly disturbed, weakened, but there was neither strabismus nor inequality of the pupils, which reacted well to light. No roaring in the ears nor decrease in acuteness of hearing, but only a vague sensation of weight in the auditory canals. He especially complains of persistent though not very pronounced vertigo. As soon as he makes a movement, even if it be not sudden, he is seized for a few seconds with giddiness so severe as to force him to sit down.

Vertigo in patients of this age may be due to several causes. Frequently it depends upon arterial atheroma; again, it may be a consequence of disturbances of hearing or gastric disorders. The diagnosis is always difficult to make, as into every variety there enters a certain auditory element—roaring in the ears—as well as a gastric involvement—nausea and a tendency to vomiting—and according as one or the other of these groups of symptoms predominate in the symptom picture, the affection is traced either to the ear or the stomach.

Now, in our patient, examination of the digestive tract only reveals a few insignificant symptoms of dyspepsia, as a little weight in the stomach after eating, sour stomach and heartburn, which are easily explained by a defective hygeine, for indeed this individual is accustomed daily to drink three quarts of wine and one or two glasses of brandy, but he presents no sign of alcoholism. Finally, there is no apparent relation between this vertigo and the empty or full state of the stomach; the hour of eating and the appearance of the vertigo. It cannot be attributed to a certain degree, though even

* Translated for THE MEDICAL AND SURGICAL REPORTER by F. H. Pritchard, M.D.

slight, of interstitial nephritis, for this man of over sixty years only rises once or twice a night to urinate; there is neither pollanuria nor polyuria; his urine is rather dark than light colored; in quantity it is not above the average and it contains neither sugar nor albumen. In short, in this patient, if we except a little emphysema, we have found the other organs, heart, stomach and kidneys, to be normal.

Only the arteries appear to be hard and serpentine, whence it would appear rational to regard the vertigo as due to congestion and similar to that variety described by Grasset as occurring in arterio-sclerotic patients. Still another symptom, formication in the fingers and hand, especially that region supplied by the ulnar nerve, permits us to trace the vertigo to the brain. There is slight decrease in muscular power in the forearm. There is no disturbance of motility in walking, and the strength of the legs is normal. Otherwise there are no signs of hemiplegia, even the most indefinite, no facial assymetry nor difficulty in swallowing. Taking into consideration the initial attack, with loss of consciousness, we are forced to admit the existence of slight cerebral congestion, with, possibly, simultaneous disturbances of the cerebral circulation of limited extent which have given rise to slight paresis of the arm. This explanation would agree with the persistence of the cerebral symptoms, but would not explain the pleurodynia which marked the beginning of the symptoms. Indeed, in cerebral hemorrhage thoracic complications are rarely immediate; they are nearly always late-appearing symptoms and dependent upon pulmonary stasis.

Thinking these symptoms of cerebral origin, we applied leeches back of the ears and gave the iodide of potash, internally, in doses of seven grains a day, to which were added local applications of opodeldoc balsam to the chest and forearm. At the beginning, the results of this treatment seemed to confirm this view, for the cerebral symptom ameliorated greatly, the headache decreased, while only a sensation of heaviness of the head with slight somnolence remained. The pleurodynia disappeared completely. On the contrary, the formication in the fingers persisted with the same degree of intensity. A second examination, made the 15th of June, disclosed for the first time a complete anesthesia distributed along the ulnar border of the forearm. In the hand it involved the little finger and the internal side of the ring finger; above it did not extend beyond the elbow joint. Sensation to all impressions was abolished. There was analgesia, thermoanesthesia, absence of the muscular sense and of articular sensibility. He had lost all knowledge of the position of his third phalanges; he does not know whether they are extended, flexed, or crossed one upon another.

How are these phenomena to be explained? It cannot be that there is a localized paralysis of the ulnar nerve, though if it corresponded exactly to the region supplied by this nerve it might be possible to admit this conclusion. But the internal side of the forearm, according to Hirschfeld, is ramified as far as the wrist by the internal cutaneous brachial nerve. Again, the upper boundary of the anesthesia does not correspond to the anatomical distribution of the ulnar nerve.

On the other hand, is it not possible to regard the anesthesia as of cerebral origin dependent upon a lesion of the cortex or the nerve centres? This view would seem to me untenable. In affections of the nuclei, a motor hemiplegia without anesthesia is observed, except where the lesion is situated in the posterior portion of the internal capsule, when there is hemianesthesia. As to cortical lesions, they are recognized as motor disturbances involving the arm or leg without anesthesia.

Attempts have been made recently to locate the sensitive zones of the cortex. Ferrier would place them in the cortex of the hippocampus major. Horsley and Schaefer in the cortex of the convolution of the corpus callosum. In support of this latter view I will cite you an observation reported by Savill, * where a man of forty-seven years had suffered for three years from convulsions. After one of these he was seized with incomplete motor hemiplegia, accompanied by anesthesia limited to the arm; that of the leg was intact. At the necropsy a tumor was found at the posterior of the hemisphere and involving the gyrus fornicatus. It therefore would not be impossible to admit a cortical origin of this anesthesia; yet this interpretation ap-

* Th. Savill: "Another Case of Anesthesia Due to Lesion of the Gyrus Fornicatus," *Brain*, lix–lx, pp. 448–451.

pears to me improbable with the absence of associated motor hemiplegia and the extensive involvement of sensation, the muscular sense and articular sensibility being lost.

Now, you are well aware that anesthesia of such extent and affecting these senses, is not remarked during the course of cerebral affections, while Charcot claimed that it is nearly always a symptom of hysteria. In our patient, in spite of the general signs which marked the beginning of his disease, in spite of his age and his external appearance, which recalls to one nothing of a subject with nervousness, yet I think that hysteria will give us the best explanation of his symptoms. Indeed, we find in him three important signs of this disease: Anesthesia of the pharynx, abolition of sensation to contact and to pain upon the left half of the face, and, finally, narrowing of the visual field. If we had not discovered these three signs we should have hesitated somewhat. Recent works have confirmed the doctrine of Charcot that abolition of the muscular sense is exclusively of hysteric origin. According to him the motor zone is exclusively motor without any implication of sensation; hence, when it is diseased, no disturbances of sensation are to be noticed. This is not, however, the opinion of the English neurologists, and notably of Charles Bastian. This latter claims that the cortical centers are endowed with a certain general sensibility and, above all, with a special sensibility by means of which one is able to appreciate the degree of effort necessary to carry out a given movement. Hence, he thinks circumscribed lesions of the cortex are capable of giving rise to a paralysis of the muscular sense. Several clinical facts go to support this view. For example, Ranson records the case of a young man of nineteen years, who, after an injury, was affected with Jacksonian epilepsy and weakness of the left arm, without atrophy and accompanied by anesthesia, analgesia and absolute loss of the muscular sense. Trepanning was followed by a complete restoration of sensation and the muscular sense. Landon Carter Gray treated an individual affected with melanotic round celled sarcoma of the brain, with right-sided progressive hemiplegia, integrity of the general sensibility, but loss of the muscular sense on the whole right side of the body. The operation, to which the patient succumbed, revealed the tumor situated in the ascending parietal convolution. Thus a loss of the muscular sense is not always necessarily associated with hysteria; it only constitutes a favorable presumption. But all doubts disappear whenever the other stigmata may be elicited, as pharyngeal anesthesia and facial hemianesthesia.

In our patient, if we admit that this disease had intervened to produce these accidents, then we may easily explain the plaque of cutaneous hyperesthesia on the thorax, which was so painful during the first days of the disease, as well as the hemoptysis, for which the most careful auscultatory examination failed to reveal a cause. You will recollect that bloody sputa have been reported where apparently no cause could be discovered, as has been pointed out by Parrot, Ferrand and Carre. Finally, the sudden beginning and the apoplectiform appearance of the affection should not mislead us, for the works of Debove and Achard on hysteric apoplexy, have taught us with what frequency the neurosis may be accompanied by apoplectic attacks, with coma, loss of consciousness, hemiplegia, etc.

In the mean while you might ask if this were not a congestive seizure coming on in a hysteric, or even a cerebral congestion simulating the principal symptoms of hysteria. The first supposition would appear to me to be the more acceptable on account of the age of the patient, the marked degree of atheroma which he presents, and the decided improvement following the use of leeches. The exciting cause of this hystero-apoplectic attack would appear to have been a passive congestion. Finally, if there be any doubt with regard to the rôle of hysteria in our patient's case, the evolution and the history would decide the question. We have learned that this individual was well and healthy until the time of the attack; that he had gone through one or two similar crises, and that he was extremely emotional. You have observed how he lamented his condition, wept without ceasing, demanded to be discharged at once, etc.; this instability of character is characteristic of hysteria.

As to explaining why this seizure came on so suddenly, we are reduced to mere conjectures. Yet the prognosis is by no means as grave as with organic lesions, though from the condition of his arteries, his age

and habits, an actual apoplectic seizure is possible later.

Treatment should aim to relieve the congestion of the brain and act upon his neuropathic state. Douches should be avoided; in one his age they would cause too intense vascular modifications. Both the bromide and the iodide of potash, combined with light purgatives, are to be recommended. The sensatory disturbances might be treated by the continuous or faradic currents.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

ANTISEPTIC TREATMENT OF DISEASES OF THE STOMACH AND INTESTINE.

Prof. Dujardin-Beaumetz (*Medicinische Neuigkeiten*, No. 34, 1894) states the chief indications for antisepsis of the stomach and intestines to be:

1. Infectious diseases especially localizing in the intestine—typhoid, dysentery, cholera, etc.

2. Infectious diseases in which the intestine is not particularly involved—erysipelas, small-pox, etc.

3. The majority of diseases of the stomach, liver and intestine within sufficient excretion of urine; also in certain heart affections.

4. Chronic and recurrent affections of the skin.

Therefore, in acute and chronic diseases the indications are very numerous. At any time when the toxines of the intestines are increased by infection or local disorder, and in cases when elimination appears impeded, antisepsis is of value.

The contra-indications concern less the method than the remedy. In kidney diseases certain drugs, as salol and naphthol, are badly tolerated on account of their irritating these organs; other remedies are contra-indicated in dyspepsia.

Antiseptic regimen: A very important factor is to prescribe a diet that will produce the least quantity of toxines in the intestines. The best foods are milk, fresh eggs, white meats, well-boiled vegetables and fruits. Soups, fish, game, preserves, cheese, etc., are to be avoided.

Constipation, one of the principal causes of auto-intoxication, must be combated by laxatives, purgatives and injections. Antiseptic irrigations act directly upon the large intestine, and for fear of poisoning, the non-poisonous antiseptics should be chosen; these are boric acid, a decoction of chamomile blossoms with boric acid, solutions of chloral, 1 to 500, beta naphthol in a very weak solution. Carbolic acid is to be entirely excluded. (A recent case of death was reported in Germany from injecting a solution of carbolic acid into the rectum.)

Antiseptics for internal use: Their number is very large. They are either soluble—resorcine, lactic acid, chloroform; or insoluble in powder form, as beta naphthol, salol or benzonaphthol.

Soluble antiseptics: Resorcine is of value chiefly in chronic enteritis and as follows:

℞ Pure resorcine..... 1 0-2 | 0 (grs. xv-xxx.)
Distilled water..... 200 | 0 (℥vjss.)
To be taken in twenty-four hours, in four doses.

Lactic acid is used in cholera and cholera infantum:

℞ Pure lactic acid ..... 2 | 0 (grs.xxx.)
Raspberry syrup. ..... 100 | 0 (℥iij ℥j.)
Water.....900 | 0 (℥xxvij.)
To be drunk in twenty-four hours in the diarrhœa of adults. In children prescribe:

℞ Pure lactic acid..... 2 | 0 (grs.xxx.)
Gum mixture.....100 | 0 (℥iij ℥j.)
A teaspoonful every three to four hours.

Chloroform water is given in fermentation in the stomach and intestines. The maximum dose is 100 grams of a saturated solution. This is diluted with one or two parts of water, according to the taste.

Antiseptics in powder form: Beta naphthol is administered in powders of 0.5 to 2.0 grams per diem, usually in combination with magnesia. The salicylate of bismuth may be given up to four or five grams a day. It is particularly valuable in diarrhœa. Betol or naphthol salicylate is prescribed in doses of one-half to two or four grams a day; the kidneys must be especially watched. Salol is especially

* In charge of the translator, F. H. Pritchard, A.M., M.D.

serviceable in biliary infectious processes: it is given in doses of one-half to a gram at a dose, and four grams a day. Benzonaphthol is best of all tolerated by the stomach and intestines; it is quite innocuous. The dose is from one-half to five grams a day; in children one to two grams, in doses of three grains (0.2), in a gum mixture.

NIGHT SWEATS OF CONSUMPTIVES.

Dr. v. Székely (*Muenchener Medicinische Wochenschrift*, No. 33, 1894) claims that the tincture of belladonna together with arsenious acid, is much more efficacious in the treatment of the night sweats of consumptives than the usually employed atropine and the other preparations of belladonna. His formula is as follows:

℞

Fowler's solution	āā 3	0	(gtts. xlv.)
Tr. belladonna			
Cherry laurel water	20	0	(℥v.)

In the evening a dose of fifteen to twenty drops may be taken, and later, during the night, another. Another remedy of which he speaks highly in this connection, and which also stimulates the appetite, is cotoin. He employs the following preparation:

℞

Cotoin	0	5	(grs. viijss.)
Water	120	0	(℥iv.)
Alcohol	10	0	(℥ijss.)
Syrup	20	0	(℥v.)

Two tablespoonfuls in the evening with an interval of two hours.

The same dose may be given in powder. Besides these remedies, the whole body should be washed with a solution of chloral (6.0–100.0) and alcohol in equal parts, or with a mixture of cayenne pepper and vinegar—one teaspoonful of the former to a teacupful of the latter. These applications are preferable to dusting powders. In some cases a little French brandy, at the most three teaspoonfuls in milk, is a good remedy for the profuse sweating. It must be used cautiously or it will increase the perspiration.

TREATMENT OF PIN-WORMS.

Dr. Nicholson (*Medicinische Neuigkeiten*, No. 34, 1894) in the treatment of pinworms in children recommends a combination of internal and local measures. A dose of santonine is given every second day for a week, while at the same time suppositories of quassia—0.6 to 0.8 to the suppository—are inserted each evening. The region of the anus is rubbed with a salve containing a little calomel and extract of quassia. From time to time a rectal injection of one ounce of olive oil containing one and a half drachms of menthol is given. The childrens' nails should be cut short so that self-infection from scratching is prevented.

STRYCHNINE AS A PROPHYLACTIC IN WEAK LABOR PAINS.

Dr. Duff (*Centralblatt f. Gynaekologie*, No. 28, 1894) employs strychnine as a prophylactic in general weakness of, and decreased muscular tonus of pregnant women, as well as in cases where there is a history of weak and irregular uterine contractions in previous labors, distinct weakness and flaccidity of the abdominal muscles, and post-partum hemorrhages from faulty contraction of the uterus. In all these cases he prescribes one milligram (1/60 gr.) of the drug three times a day, commencing six to eight weeks before the expected date of labor; eight days before the event, the dose may be increased from one-quarter to one-half. The results, he claims, are very satisfactory.

INTRAVENOUS INJECTIONS OF SUBLIMATE IN SEPTIC STATES.

Prof. Th. Kézmárszky (*Pester Med.-Chirurgische Presse*, No. 24, 1894) has employed intravenous injections of corrosive sublimate in two cases of puerperal sepsis. The first patient received, in ten injections, thirty-seven milligrams of the drug; the second, eight injections and thirty-one milligrams of the drug. In both cases there followed an astonishing amelioration of the general condition; the fever decreased and both recovered. In a case of very severe puerperal fever no result was obtained with seventeen injections, for after thirty to forty rigors it terminated fatally.

ANOTHER NEW TREATMENT OF HYDROCELE.

Dr. A. Herbing (*Centralblatt f. Chirurgie*, No. 26, 1894) describes a new method of treating hydrocele whose principle consists in the introduction of a foreign body. After disinfection of the skin, a doubled silk thread which has been sterilized previously, is introduced by means of a curved needle at the upper portion of the tumor and brought out at the lower

pole. The fluid contents are then drawn off by means of a coarse hypodermic needle or a fine trocar. Any remaining portion of the fluid is pressed out. The ends of the thread are then tied together, and the three points of puncture are touched with collodion. No dressing is necessary. The whole sac may be painted with collodion if desired. In the days immediately following, slight irritation ensues. After six to eight days the threads are removed and the punctures again covered with collodion. This method has the advantage of being simple and not requiring an anesthetic. In children it is a radical operation. In adults larger and more numerous threads must be introduced.

TREATMENT OF CRURAL ULCERS.

Dr. E. Vaugrente (*Wiener Medizinische Presse*, No. 35, 1894) describes in a recent Paris thesis a method of treating crural ulcers which is employed at Professor Tillaux's clinic, and which has the advantage of being easily applied. Treatment is both general and local. The former is directed against the cause of the usual ulcers, venous sclerosis from the diathesis, arthritism. Here the following solution is employed:

℞ Iodide potash..... 15 | o (ʒiv.)
Tr. iodine..... | (gtts. xxx.)
Distilled water.....300 | o (ʒix ʒiij.)

A tablespoonful after each meal.

This solution, if tolerated, must not only be taken until the ulcer has healed, but long after. Local treatment consists in touching the ulcer with a 5–10 per cent. solution of the chloride of zinc, for three to four days in succession. Then a compressive and occlusive bandage of strips of mercurial plaster is applied and allowed to remain on for three or four days, when it is renewed. This causes the formation of healthy granulations and soon leads to cicatrization of the ulcer. With this a cure must not be thought to have been obtained, for the cicatrix must be consolidated, which is best done by local application of a saturated solution of picric acid, applied with a brush or on compresses and covered with an impervious material. This is also assisted by exposing the scar to the rays of the sun or the heat of a stove.

ANTISEPTIC TREATMENT OF DYSPEPSIA.

Prof. Dujardin-Beaumetz (*Medicinische Neuigkeiten*, No. 34, 1894) in the antiseptic treatment of dyspepsia recommends the three following formulæ; the former two in dyspepsia with diarrhœa, the latter in the same affection when associated with constipation:

℞ Beta naphthol.....
Salicylate bismuth.....
Magnesia or powdered rhubarb. } āā 10 | o (ʒijss.)

Sufficient for thirty powders. Two to four a day.

℞ Salol.....
Salicylate bismuth.....
Bicarbonate soda..... } āā 10 | o (ʒijss.)

Sufficient for thirty powders. Two to four a day.

℞ Salol.....
Benzonaphthol.....
Magnesia..... } āā 10 | o (ʒijss.)

Sufficient for thirty powders. Two to four a day.

ICHTHYOL IN ACUTE PHARYNGITIS.

Dr. Sonnenberg (*La Semaine Médicale*, No. 52, 1894) states that he has found the most efficacious treatment of acute pharyngitis to consist in having the patient gargle, every ten to fifteen minutes, with a 2–3 per cent. solution of ichthyol. In forty cases where he employed this treatment the inflammatory phenomena disappeared in twelve to twenty-four hours.

COPPER AS A HEMATIC REMEDY.

Prof. Cervello (*La Semaine Médicale*, No. 52, 1894), of Palermo, Italy, claims that copper possesses hæmatogenic properties similar to those of iron. He administered the sulphate, in doses of six milligrams per diem, mixed with sugar of milk, to patients with malarial cachexia. He also recommends it in anemia and especially in chloro-anemia.

TO REMOVE RUST FROM SURGICAL INSTRUMENTS.

Dr. Saenger (*Hospitals-Tidende*, No. 36, 1894) praises the following measure to remove rust from instruments. The instrument is placed into a saturated solution of the chloride of tin over night, and then taken out and washed off in hot water with a soda soap.

CORRESPONDENCE.

CHRISTIAN SCIENCE.

EDITOR MEDICAL AND SURGICAL REPORTER: In the very brilliant paper published in your journal of September 22d by Dr. S. S. Towler, regarding a little criticism I made of Dr. Longsdorf's paper on "Christian Science," I very unintentionally "touched the doctor on the raw." The doctor is right. We will forget that we are dealing with "timid, modest maidens," and perhaps say things that we had better left unsaid.

I am heartily sorry, Dr. Towler, that I was deprived of the pleasure of hearing the remarks you so thoughtfully favored the society with after the reading of Dr. L.'s paper.

You have been jumping at conclusions. I am not an upholder of "Christian science" in its literal sense, as a glance at my article in THE MEDICAL AND SURGICAL REPORTER of September 29th will testify (this article was read May 9th, before Dr. L.'s), in which I suggest that the patient's mind needs a little more attention than is usually paid to that important part of man. But I will protest against legislating away the right to cure a class of neurotic unfortunates who are being slowly cut and dosed to death. Who is at fault? Either patients do not have faith in their medical advisers, or else the latter have failed in their diagnosis.

Thank you, doctor, for the report of your case. If I had talked a week I could not have given a better example of "faith cure." By the way, doctor, that tallow-candle story has a similarity to a story told of Dr. S. Weir Mitchell.

Yours truly,

J. NEWTON HUNSBERGER.

SKIPPACK, PA.

STERILE PUS IN HEPATIC ABSCESS.

M. Rendu related the case of a woman, aged 51 years, who entered his service, February 10th, for an abdominal affection, the diagnosis of which was obscure. A month previously the patient, until then healthy, had experienced pain in the right iliac region, accompanied by vomiting, diarrhœa, and fever. When she entered hospital the vomiting and diarrhœa had ceased, but the fever persisted, with chills and considerable enlargement of the abdomen; the liver was enlarged and the entire perihepatic region pa nful. The lungs were also the seat of iconsiderable congestion, and the general condition of the patient resembled that of a person suffering from typhoid fever. M. Rendu diagnosed the case as one of infectious enteritis with secondary congestion of the liver and lungs. At the end of several days there was much improvement in the abdominal symptoms, but the state of the lung became aggravated and signs of broncho-pneumonia soon appeared. The patient, however, lived for some time, and death followed from cachexia due to inanition.

At the autopsy a portion of the intestines was found agglutinated, and the vermiform appendix bathed in a small quantity of thick, greenish pus. The cæcum was the seat of numerous partly-cicatrized ulcers, while the liver was filled with small cavities varying in size from that of a hazel-nut to that of a walnut, and containing pus. This pus was found, on examination, to contain chains of cocci exactly resembling the streptococcus pyogenes. Other specimens of the pus were subjected to culture, some in agar, some in bouillon. All remained sterile and could not be cultivated. Thus, a pus morphologically containing infectious microbes showed itself to be practically sterile, proving that we are not in a position to state positively that the pus of an old abscess, which does not contain micro-organisms at the moment of examination, did not primarily contain them. It is difficult to say why the microbes of hepatic suppuration may thus lose their virulence and become sterile; but it may be reasonably asked whether the liver, which in a healthy state serves as a filter for toxins, does not exert a salutary action also upon the pyæmic infarcts developing within its parenchyma.—*Semaine Médicale—Univ. Med. Jour.*

EDITORIAL.

OLIVER WENDELL HOLMES.

Shortly after noon, Sunday, October 7th, without indication of pain or semblance of struggle, Dr. Oliver Wendell Holmes died, practically of old age, at his home in Boston and surrounded by the members of his family. His death was as his life—peaceful and beautiful. For several years Dr. Holmes is reported to have been afflicted with asthma, and his return to the city from his country home ten days previous to his death caused a particularly severe attack of this malady. He had recovered, however, from the acute attack, but it left him very much broken. Never robust, he had lived to the great age he did through having taken the best care of himself at all times; but the power of recuperation was gone and his vitality was exhausted.

Oliver Wendell Holmes was born in Cambridge, Mass., on August 29, 1809. His father was the Rev. Abiel Holmes, a, clergyman of Cambridge and a historian who is said to have made the first attempt at writing a history of this country in his "American Annals." His great-grandfather was John Holmes, one of the old Puritan stock who settled in Woodstock, Conn., about 1686. Oliver Wendell Holmes inherited his father's literary instinct and very early began to write verse. At college he became the editor of the college magazine, and at the age of twenty-one, the year after his graduation, the agitation over the announcement of the intended destruction of the old war frigate Constitution began, and he wrote the well-known poem "Old Ironsides," which was published in the Boston *Advertiser*. He became famous at once. He had struck a popular note, and the tide of public opinion set strongly against the destruction of the vessel.

As a boy at Phillips' Academy, Holmes translated the "Æneid." After graduation from college he turned his attention first to law, but never practiced, and later took up the study of medicine. He spent three years in hospital study, and practiced in Edinburgh and Paris, and in 1836 he received his medical degree. In that year he published his first volume of poems. He always continued to make medicine his profession, but early made literature his diversion, and as a poet and author

became known to the people. He accepted the Professorship of Anatomy and Physiology at Dartmouth College in 1839, and later practiced medicine in Boston, where he married Amelia Lee Jackson, daughter of Judge Charles Jackson, of the Massachusetts Supreme Court, by whom he had two sons and a daughter. In 1847 Dr. Holmes was made Professor of Anatomy at Harvard, a chair in which he continued until 1882, when he resigned, and was made Professor emeritus. President Eliot paid this tribute to his skill: "There are 3,000 men throughout New England who will remember Dr. Holmes through their lives, and transmit to their children the memory of him as a teacher of exact science."

Dr. Holmes wrote forty-two works on medical subjects, and lived to see many of his early ideas of medicine, which at first met with condemnation, accepted by leading physicians of the world. Speaking of this recently, Dr. Holmes recalled the storm of indignation which was raised by his famous epigram that if all the medicine in the world were thrown into the sea it would be all the better for mankind —and all the worse for the fishes. And then he laughed quietly as he remarked that now most of the profession practically agreed with him.

In 1857, when the *Atlantic Monthly* was started, Lowell asked Dr. Holmes to contribute to it. So he began "The Autocrat at the Breakfast Table" essays, which obtained immediate popularity, and the success of the magazine was assured. "The Professor at the Breakfast Table" (1860) and "The Poet at the Breakfast Table" (1873) followed, and then after long years came a number of papers in the same vein in the new *Scribner's Magazine*. "Over the Teacups," which appeared a few years ago, was made the occasion of the announcement by Dr. Holmes that it would probably be the last of the series.

Dr. Holmes was a sociologist, though he was not often recognized as such. In the only two novels which he wrote, "Elsie Venner" (1861) and "The Guardian Angel" (1868), his skill in dealing with social problems was shown. "Elsie Venner" was a curious study in heredity.

Mature in mind in early years, Dr. Holmes in age was young in thoughts. More than thirty years ago at a class gathering he said:

"Has there any old fellow got mixed with the boys?
If there has, take him out without making a noise.
Hang the almanac's cheat and the catalogue's spite!
Old time is a liar! We're twenty to-night."

And more than forty years ago he said to young men:

"Be firm—one constant element in luck
Is genuine, solid, old Teutonic pluck.
Leave what you've done for what you have to do;
Don't be 'consistent,' but simply true."

When lectures were popular, forty years ago, Dr. Holmes was in demand on the platform and was ever full of philosophy and fun. Lowell said this of him:

"There is Holmes, who is matchless among you for wit,
A Leyden jar always full charged, from which flit the electrical tingles of hit for hit."

Whittier paid tribute to Dr. Holmes in more sober verse, and but a little while ago Dr. Holmes referred publicly to "my friends Whittier and Bryant," whom he had outlived.

Dr. Holmes was a successful practitioner and a popular teacher of medicine, and the medical profession has always been proud of the fact. But it is not as a physician that Dr. Holmes attained the preëminence to entitle him to be called great. If it were possible to separate the literary man from the physician, his work in his scientific profession would not rank him among great physicians. It is a benefit to civilization in general, if not to the world of science, that Dr. Holmes achieved his greatness in the world of letters, as it is the loss of the author, not the physician, that has produced such profound sorrow the world over.

Commenting upon the subject, a writer in the *Tribune* says: "The death of Oliver Wendell Holmes, a natural event at his great age, but not the less a sorrowful bereavement, is the extinction of one of the most remarkable men of this century. Holmes may have been, in the characteristics of humor and fastidious taste, a disciple of the wits of the age of Queen Anne, but in the essential fiber of his intellect—its calm courage, its broad vision, its ample equipment, its eager, joyous, sanguine vitality—he was emphatically a man of the present day. He sympathized to the fullest extent with the march of thought, and in every direction of advance he stood in the front line. As a writer he ranged over many fields, and in all of them he manifested not only copious and various mental resources, but two of the greatest qualities that exist to dignify the human

mind and to help the human race—lucid perception and dauntless cheer. He knew the world as it is; he saw everything; and he was neither dismayed nor saddened. At all times and under all circumstances he spoke for the nobility that is in man and the spiritual grandeur to which man is naturally destined; and his voice always rang out, clear and bravely, the inspiring watchwords of labor and hope. Whether in essay, novel, or poem, or treatise, or history, or speech, his indomitable spirit was always present; and thus, while dispensing the force and beauty of thought, the pleasantness of mirth, and the gentle light of humor, he imparted the benefit that is needed most of all, the blessing of strength. The reader of Holmes receives a continual impulse toward the steadfast, cheerful performance of duty; a continual incentive to unquestioning faith in the final prevalence of right; and therefore the world is better and happier because he has lived in it.

"There will, doubtless, be discussion, as time flows on, with reference to the rank of Holmes as a man of letters, but there will be no discussion as to the influence that he exercised; and perhaps no question is of much practical importance that can be raised concerning any writer who has helped his generation to bear its burdens and to do its work. The literature that is permanently valuable to the world is that which transcends personal expression and enters into the general life. Holmes, by his 'Autocrat' alone, reached thousands of minds—filling them with liberal ideas and kindly views; stimulating their finer propensities, and generally prompting them to look at all things in a tolerant mood, to be merciful as well as just, and to lighten the toils and troubles of this transitory life with mirth and laughter. In this respect he did not leave his place to be determined by controversy, but took it, and held it, for himself. He was, most of all, a humorist; and furthermore—which is exceptional and extraordinary—he was a humorist in a new vein; for he did not stop at character and manners, but ranged through the whole wide realm of philosophy, and, with the deepest appreciation as well as the liveliest fancy and the most genial pleasantry, played about the gravest subjects that can occupy our thoughts. Born and reared in the intellectual period of Emerson, he felt, with that great spirit, that 'the solar system is not sensitive to criticism,' and, with a spontaneous drift toward goodness and beauty, he neither darkened his vision nor restrained his speculative faculties, nor put the least curb upon his exuberant humor. His 'Autocrat,' therefore, is one of the most natural books written—a book that teems with stimulative suggestions, and one that has helped, to a high degree, to emancipate the age from many fetters of bigotry, conventionality and folly.

"Holmes himself valued his humorous writings less than he valued his poetry. Indeed, it was as a poet that he chiefly desired recognition and remembrance; for he was well aware that all his powers derived their vitality, lucidity and harmony from the poetic principle that was at the basis of his mind. To how great an extent poetic emotion was controlled in him by his very vigilant faculties of sense and humor, and by the circumstances of his conventional environment, it would not, perhaps, be easy to determine. That it was so controlled, and that he often felt it to be so, is manifest. No writer has suggested so sadly, so pathetically, the strains, surpassing all earthly music, that die away unheard in the viewless temple of the soul. The crowning excellence of his verse is felicity. He had inspiration—as when he wrote 'The Chambered Nautilus,' 'The Voiceless,' 'The Iron Gate,' 'Under the Violets,' 'Martha,' 'Nearing the Snow-Line,' and that exquisite tribute to Moore, which is certainly one of the best poems of occasion that ever were written. But his inspiration does not seem to have been constitutional, and perhaps he was more a poet by art than by nature. He possessed, however, a prodigious moral fervor, combined with the torrid glow of a brilliant intellect and with great sensibility, and he was a supreme master of style. No man has ever spoken better the word that it was in him to speak.

"With the extinction of Holmes, almost the last of the literary lights of New England has disappeared. It was a noble group. Dana, Percival, Emerson, Hawthorne, Longfellow, Whittier, Willis, Curtis and Holmes—all sons of a Puritan commonwealth, all children of the Muses, all famous, and all at rest. What a wealth of genius, of aspiration, of beautiful character, and of noble living those names de-

note! and what a wonderful variety of faculties and achievements! In all the luminous circle there was no heart more true and tender than the heart that is now stilled forever; no spirit so bright as the spirit that now has passed into that awful darkness and silence where only the eyes of love and hope can follow."

ABSTRACTS.

THE IMPORTANCE OF EARLY DIAGNOSIS IN LATERAL CURVATURE OF THE SPINE.

Dr. Benjamin Lee, in a paper with this title, said: "Every orthopedist is aware of the difficulty of successfully treating a confirmed case of lateral curvature. The mechanical problems involved are of so complex a character and the tissues affected are of so unyielding a nature as to make complete restoration of symmetry in the majority of instances an impossibility.

"The large majority of cases of this diseases occur, as is well known, in growing girls. Apart from all considerations of physical suffering and ruined health, the woman who is fated to go through life with a humped shoulder and a twisted torse is doomed to constant humiliation, mortification, and disappointment. It is worth while, then, to attempt to prevent at least a portion of this torment of body and anguish of heart and mind. I know of but one way in which this can be accomplished, and that is by taking cases in time, before the skeleton has become so set in its abnormal position that the application of even powerful mechanical apparatus is able to effect but little change. In order to take them in hand thus early we must, first, be able to recognize them, and, secondly, put ourselves in a position to recognize them.

"Absolutely no intelligent conclusion can be arrived at by cursory and imperfect methods of investigation. In order to determine the presence of lateral deviation, we shall look not at the spine itself, but at the contours of the two sides. We must see the entire back from the head to the cleft of the nates.

"In order to detect incipient rotation we must carefully examine the comparative position of the transverse processes on either side. This is done by placing the forefinger of each hand, held as nearly flat as possible, on each side of the spine at the level of the vertebra prominens, and slowly and with equal pressure passing them down, side by side, over the lateral processes, as far as the sacrum.

"If, at any point, one finger begins to approach the observer while the other recedes from him, there is rotation at that point, and if such alteration in the position of the fingers takes place in reverse directions at two different points, then a compensatory curve has begun to form."—*College and Clinical Record.*

Tampons in Menorrhagia.

Dr. W. T. Lusk strongly urges (*Amer. Jour. Med. Sc.*) the employment of the tampon in cases of uterine hæmorrhage where the curette shows no endometrium disease. He has found it especially serviceable in young patients. The tampon should be used according to the Dr. Sims method. It should be made of cotton soaked in carbolized water, and compressed into flattened disks. By means of the Sims speculum, these should be applied firmly to the vaginal vault, and should be continued to the urethro-vaginal septum. The tampon should be removed at the end of twenty-four hours, the vagina irrigated, and a fresh tampon introduced. Not more than two or three applications are usually needed. Under this treatment, normal muscular tone is restored, and the tampon can be dispensed with.

Otaheite Orange.—This plant is cultivated exclusively for ornamental purposes on account of its propensity to bloom continuously. Its handsome little fruit is not particularly desirable for eating.

SOCIETY REPORTS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of September 12, 1894.

Dr. M. Price reported

A GROUP OF CASES COVERING ALMOST THE ENTIRE FIELD OF ABDOMINAL SURGERY.

(See page 444.)

DISCUSSION.

DR. J. M. BARTON: Dr. Price reported one case where he removed the uterus because it produced obstruction of the bowels, the patient being in collapse at the time of the operation. Under these circumstances the usual surgical procedure would be to make a temporary artificial anus by a small abdominal incision, to bring out a single loop of the distended bowel, the distention showing it to be above the obstruction, and to open it at once. This is the method of Mr. Treves, and is one I have used with some success on several occasions. If the patient rallies, extirpation of the uterus or such other radical surgical procedure as may be required may then be resorted to, with the patient in a condition to stand the operation.

There is one point I would like to call attention to in the appendicitis operation reported. I understood the doctor to say that he does not close any portion of the abdominal incision. If not closed it is very liable to be followed by a hernia. In my earlier operations I had several cases of hernia, but in my later cases I have been fortunate enough to avoid this by using the gauze not as a drain, but only to isolate the rubber drain and by at once closing nearly all the wound.

If the pus is deep I make the opening through the abdominal walls not less then four inches in length, and after opening the abdominal cavity, and before opening the abscess or attempting to remove the appendix, I p event infection of the general peritonea' cavity by surrounding the place where I propose opening the abscess with gauze, packing it under the edges of the incision so as to keep the movable intestines away from the wound and the danger of infection from the pus. The abscess is then opened and two rubber drains introduced to the bottom of it, and the abdominal wound closed by the interrupted suture, allowing only the ends of the rubber drains to protrude, the gauze is left inside, with only a corner showing, by which to seize and remove it on the third or fourth day.

The two stitches next the rubber drains are tied in a bow-knot so that they may be readily retied, if they have to be loosened to remove the gauze. All the cases in which I have used this method have recovered without any hernia whatever.

Of course, if the abscess is in contact with the anterior abdominal wall and the general cavity shut off by adhesions, no gauze packing in necessary, and the short incision such as Dr. Price mentioned is quite ample.

DR. ERNEST LAPLACE: I share the opinion of Dr. Barton that in chronic cases of appendicitis, where pus is isolated from the general peritoneal cavity, the more we treat the condition as one of abscess the more successful we will be. A small incision is not as good surgery as laying the abscess freely open so as to see what we are doing, not tampering, however, with the posterior wall of the cavity. Then the walls should be cleaned and irrigated and the cavity packed gently with iodoform gauze. This gauze should be removed and replaced the following day. The more thoroughly we are able to apply the theory of asepsis the better will the case behave.

I take it that we cannot be too cautious in treating cases of chronic appendicitis. We must look at it as nothing but an abscess, and never look for the appendix unless it is to be easily found. If it is not removed it will do no harm and be imbedded with the rest of the cicatricial tissue during the healing process.

DR. MARIE B. WERNER: There is one part of the paper which interested me very much, and that is the question of the mental state in pelvic disease. About

two years ago I made some investigations, as far as I was permitted, at the Norristown Insane Hospital. I examined thirty cases and found 50 per cent. suffering from pelvic disease of some sort. Some, no doubt, would have been benefited by local treatment, others by operation. There were two on which I operated. One was a case of double hydrosalpinx. The patient had been insane since 1888. The operation was done in July, 1892. The patient is now, so far as I know, perfectly sane. This patient was seen by Dr. Thomas G. Morton, after dismissal, who verified my present statement. She left the hospital about eight weeks after operation. In the second case there was a cystomatous degeneration of one ovary and tubercular disease of both tubes and ovaries. The patient had had several attacks of insanity, and had been in Kirkbride's three times. Each attack had been preceded by an attack of pelvic inflammation. In this case the ovaries and tubes were removed, and the patient made a rapid and thorough recovery. I saw her afterward in her own home, and she was well not only physically but mentally.

I am sorry that I cannot speak of more than two cases, but these two cases show that there is a wide field for work of this kind. I do not wish to be understood as pleading for the knife entirely; I plead for thorough investigation and good treatment in these cases. In my own practice I have met with several cases which led me to think that much could be done in that direction. One which I distinctly remember occurred in my early practice. The patient was a young woman who felt that she must leave her baby or else she would kill it. She suffered from a laceration of the cervix and a complete laceration of the perineum. I repaired the lacerations, and she got well, but how long the cure lasted I cannot say, because she drifted out of my sight. It certainly lasted a few years.

Dr. J. M. Baldy: I did not care about discussing the paper; but since such emphasis has been laid on the nervous phenomena in connection with fibroid tumor, I should not like the statements to go out from the society apparently sanctioned by my silence. In a very large number of fibroid tumors (hundreds) I have not seen one in which there was any insane symptoms. Thinking over my cases, I should say that they are decidedly more free from nervous phenomena than any other class of gynecological cases; certainly more than the pelvic inflammatory cases. As to insanity being due to gynecological troubles, I have a number of times been called to insane hospitals to see patients whose friends were possessed with the idea that their insanity was due to pelvic disease, and in not a single instance have I found the slightest disease to which the insanity could be attributed. I do not believe that the subject has anywhere near the importance that has recently been attempted to be given to it.

Dr. W. Easterly Ashton: In a large experience with fibroid tumor I have certainly seen no symptoms that would in any way point to a disordered state of the mind. It is true that some of these women are nervous, but any one would be nervous suffering from constant pressure. Outside of the nervousness caused by the physical inconvenience of the tumor, women have no mental symptoms.

It seems to me that the statement of Dr. Price in reference to fibroid tumors causing insanity is in line with another idea that has been advanced in regard to these growths, namely, that all fibroid tumors should be removed by operation. I am far from convinced that every fibroid uterus should be removed. The idea of insanity associated with fibroid tumors seems to be an additional plea for this form of surgery. As long as a fibroid tumor of the uterus is small and uncomplicated by pelvic trouble, I see no reason why the woman should be subjected to abdominal section. The tumor should be carefully watched, and if it grows or shows signs of inflammatory changes, then it must be removed.

Before I sit down I should like to ask Dr. Price for an explanation. Last spring at one of the meetings of the Obstetrical Society I made some remarks on the exploratory incision, and made the statement that in a large percentage of obscure cases I would give very little for the positive diagnosis of any surgeon. Growing out of this statement Dr. Price stated that in no instance had he ever opened the abdomen unless he could put his finger on the disease. I would, therefore, ask what led him to operate on the case of suspected appendicitis, if the diagnosis was uncertain?

DR. G. BETTON MASSEY: I can add my testimony in regard to the absence of any special mental manifestations in association with fibroid tumors. Out of a large number of cases I can recall none that presented such manifestations or more than the usual eccentricities of chronic illness. I wish to say, in regard to pelvic operations for mental disease, that there certainly is danger of overdoing them, and I speak from a medical experience of three years in a hospital for the insane. I must, however, temper my remarks by saying that as yet the gynecologic treatment of the insane is an untried field in most of these institutions, and we should welcome any evidence of an increased scientific spirit among them.

Dr. Werner mentions a case where repair of the cervix and perineum was done in a case of puerperal insanity, and the patient got well. My view of puerperal insanity is that it is not due to an irritation such as that, but is an infectious disease. The disease is frequently curable of itself in six weeks. Possibly the criticism might apply to other cases also that they were not of the ordinary chronic type of insanity.

DR. JOHN C. DA COSTA: I agree with what has been said by Dr. Baldy and Dr. Ashton in regard to insanity not accompanying fibroid tumor. I do not think that Dr. Price meant to say that all these cases of fibroid tumors were accompanied by insane symptoms. I rather think that he intended to say that they were sometimes accompanied with nervous symptoms of a profound character. Where you have a woman with a tumor in the abdomen which she knows has to be taken out, she naturally will be nervous until she has made up her mind positively that it has to be removed. My experience has been that so far as mental derangement is concerned—not nervousness—cases of fibroid tumor have been free from it.

In regard to operation in these cases, I agree with Dr. Ashton as to the propriety of letting small fibroids alone. When they grow rapidly or threaten malignancy it is time enough to take them out. I have now under observation cases of fibroid where I consider that operation would be so dangerous as to threaten life, and I am sure that by proper management they will tide over the menopause and get well if let alone.

DR. WERNER: I wish to state that the case in which I repaired the perineum and cervix was one that did not occur in my own practice as an obstetric case. She fell into my hands a year after the child was born, so that it could not properly be called an *acute* puerperal case.

DR. PRICE: Replying to Dr. Ashton, I would say that if he looks over the case of appendicitis he will find that I put my finger on what I was going to remove. I knew that there was a diseased ovary and a diseased appendix—cut for it, and removed it. I think that for eight years I have never done an exploratory operation. I have never opened the abdomen to make my diagnosis, yet Dr. Ashton is in a measure correct. In abdominal surgery exactness is impossible, but a man who is not able to say when he has a big ovarian tumor or a big fibroid is certainly deficient in diagnostic ability, and should not operate until he is sure he has something to remove.

In regard to fibroid tumors of the character that Dr. Massey mentions, I never see them. The patients never come to me until they are distressed by the condition and are suffering. In the thirteen cases reported there was not one in which the tumor was not larger than my head. When a tumor is of the size of a cherry-stone to that of a lima bean, such as Dr. Massey tells us about, I think that the knife should not be used. I agree that they are electric cases if you can find them, but no one but an electrician can detect them. I think that if the cases of extensive fibroid disease are carefully examined it will be found that a number—I do not say all or nearly all—of them have mental symptoms that are marked and border closely on the line of insanity. I do say that of the pelvic cases with suppurative disease, any number of them are to-day in our insane asylums, and the list of insane could be materially diminished if these cases were properly treated. I agree with Dr. Werner when she says that she does not advocate the knife in all of these cases of insanity; but if you can put your finger on the thorn that has driven that woman with pain and suffering to the mad-house, remove it. They are there by the hundreds, and operators throughout the country are saving hundreds from going there. If any one of you had a mass of pus in your abdomen with ad-

herent omentum and bowel racking your constitution, your chances of going to the insane asylum would be ten times greater than they are now. I do not say that this condition of itself produces insanity, but it greatly predisposes to it. We can prove it by a number of cases that have come into the house insane and have gone out sane.

With regard to appendicitis, I think that Dr. Barton and Dr. Laplace misunderstood me. I agree with those gentlemen except as regards the incision. I have had twenty-three cases with two deaths. One was a case of Dr. Collins', which could have been saved if they had listened to Dr. Collins. The second case died of sepsis present at the time of operation. In two cases the appendix was removed. These were median operations. When the appendix is to be removed I believe that it should be a median operation. Where you remove the appendix the symptoms of abscess are not so marked, but you have symptoms of obstruction of the bowel. Here you have to make a median incision in order to detach the adhesions. If you find that the abscess is mapped off from the peritoneal cavity you can make a drainage incision above the crest of the ilium. In the cases that fall into my hands there is generally a well-marked abscess, and drainage is the only indication, and no effort is made to find the appendix.

I think that the practice of packing the whole abscess with gauze is unsafe. I think that if these cases are opened, irrigated, and a gauze and rubber drain put in, the gauze being replaced every twelve or twenty-four hours, they will all get well. I do not care if the whole head of the colon is gone, they will get well without a fecal fistula. I have seen large quantities of feces pour out for eight or ten days and the opening finally close. If you make the incision too long you may go beyond the abscess cavity and get into the abdomen. A two-finger opening will enable you to do all that is necessary.

FISH-BONES IN THE THROAT.

Dr. Adolph Rupp (New York *Medical Journal*) says:

The reasons for the impaction of foreign bodies, such as fish-bones, needles, pins, and the like, are not to be sought for in the pharynx primarily.

Under normal conditions, the tongue, fauces, and pharynx, in so far as deglutition is concerned, are perfect organs, looked at as a mechanico-physiological apparatus.

The primary and chief cause of fish-bones, needles, etc., being caught or entangled in the throat, must be looked for in the bolus itself—the position of the fish-bone or needle in the bolus, whether lying deep or on the surface, the angle the fish-bone or pin occupies to the long axis of the bolus, and, besides, the varying and various forces that act on the bolus as it is forced toward the stomach.

Possibly the bolus leaves the tongue and descends the pharynx with a twist or screw-like movement.

The Falk-Kronecker-Meltzer conception of deglutition, based on experimental results, may be utilized in explaining how fish-bones become impacted in the throat—and these experimental results do not exclude the element of gyration as one of the forces that impel the onward-shooting bolus.

The epiglottis is an indifferent organ in so far as deglutition is concerned—also for foreign bodies.—*American Lancet.*

The Contagion of Mumps.

Le Courrier Médicale gives some interesting information concerning mumps. The incubation period varies from eight to thirty days, but in the majority of cases the duration is from eighteen to twenty-two days. It is especially contagious during this period, but is also contagious for some time after cure. The exact length of time has not yet been determined. The parotid and testicular fluids and also the blood appear to contain a certain pathogenic organism, but as yet this point is unsettled. Hitherto the results of inoculation with this special microbe have been negative. Frequently the disease begins with tumefaction of the submaxillary glands and a severe angina. Sometimes in metastatic orchitis the swelling begins with an epididymitis.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE AMERICAN JOURNAL OF OBSTETRICS

for September. Dr. John Young Brown, First Assistant Physician Central Kentucky Asylum for the Insane, discusses

Pelvic Disease in Its Relationship to Insanity in Women.

The author holds that simple neurosis is not an indication for operation. "In this day of conservatism," he says, "with the knowledge we have of the symptoms and pathology of pelvic disease, the indications for an operation in a given case are to be based on the local diseased condition of the organs and the symptoms resulting therefrom, and not on any supposed reflex symptoms. I hold that no surgeon has a right to remove the uterine appendages from a female lunatic unless there is present a pathological condition which would warrant an operation in mental health." From his own observations in the asylum with which he is connected, he is convinced that examination will show that fully twenty-five per cent. of the female population of our State institutions suffer from some form of pelvic disease.

The report includes the report of four operations performed by the author, with three recoveries to health and one failure, a case of nymphomania.

Dr. Charles N. Smith, Gynecologist to St. Vincent Hospital, Toledo, Ohio, reports a "Total Extirpation of the Uterus for Myofibroma Complicated by Pregnancy." The operation performed, that of total extirpation, is not recommended as a routine practice, although it seemed best in this instance. The patient made a good recovery.

Dr. Helena Goodwin, of Philadelphia, reports a case of "Pregnancy Following Ventral Fixation of the Uterus." The patient had had three children and ventral fixation had been performed for retroversion after the birth of the third child. She had had attacks of "inflammation" after each confinement and again after the operation. At the end of the fourth gestation the uterus was firmly attached to the anterior abdominal wall, rendering the application of an abdominal binder necessary. The labor was a breech. Following this the patient had an attack of inflammation as before, and five months after delivery the reporter performed a section for the removal of the right appendages, with ultimate recovery of the patient.

Dr. Frederick A. McGrew, Instructor in Physiology Rush Medical College, reports "Three Cases of Nephritis in Pregnancy," with two recoveries and one maternal death.

Dr. Rufus B. Hall, of Cincinnati, presents the "Clinical Report of Four Cases of Appendicitis: Operation and Recovery."

Dr. Richard Douglas, of Nashville, describes "A New Vaginal Speculum" devised by him.

Dr. Howard A. Kelly, Professor of Gynecology and Obstetrics in the Johns Hopkins University, contributes a paper on "Electric Illumination of the Field in Abdominal Surgery," describing the various forms of lamps used by him in his work.

The remaining paper, "The Etiology, Pathology, and Treatment of Intestinal Fistula and Artificial Anus," by Nicholas Senn, M.D., Professor of Practice of Surgery and Clinical Surgery in Rush Medical College, etc., has already appeared in THE MEDICAL AND SURGICAL REPORTER of September 22d, page 390.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for October. Dr. Landon Carter Gray, of New York, contributes a lengthy paper on

Persistent Albuminuria and Glycosuria, with Frequent Hyaline Casts, in Functional Nervous Diseases.

The author states that he has been accustomed for many years to have urinary examinations made in cases of neurasthenia for fear of overlooking some lurking renal trouble. In this way there have been examined 31 cases of neurasthenia, 1 case of subacute mania, 2 of Raynaud's disease, 2 of hypochondria, 1 of *folie de doute*, or mysophobia, 5 of melancholia, 4 of vertigo, 1 of lumbago, 1 of diabetes mellitus, 1 of spinal syphilis, and 3 of hemiplegia. In all of these cases tests have been made for albumin, sugar, urea, the phosphates, uric acid, calcium oxalate, casts, and indican; and in many cases the urine has been tested for nucleo-albumin from the bile, for serum-globin, fibrinogen, urobilin, and bile. In most of these cases, albumin, sugar, excess of phosphates, oxalate calcium, uric acid, and indican have been found. The author states that he has found Millard's test to be a much more reliable one than that by heat and nitric acid, inasmuch as he has frequently failed to find slight amounts of albumin by the latter, when they have been found by the former; while on the other hand he has never failed to find albumin with heat and nitric acid, when it has been demonstrated by Millard's test. For sugar he believes the indigo carmine test to be the most delicate and reliable. For reasons given at length in the paper the author believes that the following conclusions are justifiable:

1. Many functional nervous diseases, especially neurasthenia, can constantly or well-nigh constantly be accompanied by albuminuria, glycosuria, excess of uric acid and oxalate of lime, and occasionally by excess of urea, indican, and hyaline casts.

2. It is probable that these urinary products are results rather than causes of disease.

3. These conditions very probably represent what has been called lithæmia.

4. It is probable that many, if not most, of these cases are not cases of early nephritis.

5. It is possible that there are different albumins in the urine, and that upon the determination of these will rest the future diagnosis of nephritis from other diseases.

In the treatment he has not found any advantage from any one system of diet. The light cases without mental or nervous symptoms or digestive symptoms are best treated by nitro-muriatic acid; or in some instances by nitro-muriatic acid before meals and from 2 to 5 grains of salicylate of soda after meals. Laxatives should be used with care—usually the author has found Rochelle salt to be sufficient, in doses of a drachm in a tumbler of water before breakfast. The cases in which there is intestinal disturbance he divides into two classes: Those in which there is intestinal disturbance alone and those in which the intestinal disturbance is accompanied by mental or nervous symptoms. For the intestinal disturbance he has long given up the use of pepsin, as he believes it only relieves temporarily, and its continued use will often aggravate. Sometimes pancreatin will do good, but he states that his patients have derived more good from the subgallate of bismuth, salol, calomel, subnitrate of bismuth, codeia, laudanum, and salines. Of these he believes that subgallate of bismuth and salol are the most effective, in doses respectively of 5 and 2 grains three times a day. It is usually of advantage to preface their use by a few doses of calomel, say 2 grains at bedtime for one or two nights or 1-10th of a grain given every hour for four or five hours. Where the nervous symptoms are present he adopts a modification of Dr. Weir Mitchell's rest treatment. He has abandoned massage, as he thinks that in many cases of neurasthenia it actually prolongs the weakened condition, while he has seen it aggravate cases of melancholia.

Appended to the paper is the description of the chemical tests employed in the urinary examination.

Dr. Willy Meyer, Professor of Surgery at the New York Post-Graduate Medical School and Hospital, etc., discusses

Recent Methods of Gastrostomy for Stricture of the Œsophagus.

The author sums up his paper as follows:

1. There are now three useful and reliable methods of gastrostomy at the surgeon's disposal. Of these, one (Witzel's) prevents leakage with absolute certainty. The two others, if properly carried out, promise the same good result. Thus the patient who has been submitted to this operation will not starve from regurgitation of the food alongside the tube.

2. In view of this fact, gastrostomy should be resorted to "early" in cases that will sooner or later need this operation.

3. In cases of burn of the œsophagus, primary gastrostomy and timely dilatation of the contracting scar will most probably prevent conditions which at present generally confront the surgeon in this class of cases, and are sometimes incurable. Witzel's method of gastrostomy deserves preference. The oblique canal produced by it will close spontaneously when the tube has been removed. Thus a secondary operation will not be needed.

4. In cases of cancer of the œsophagus a gastric fistula should be established as soon as the scales show a steady decrease of the patient's weight.

5. Further experience is needed with reference to Ssabanejew-Frank's method before an attempt is made at giving each of the three operations its proper place in the treatment of cancerous stenosis. If future observations be favorable, Ssabanejew-Frank's operation seems to be destined to become the standard one for malignant stricture of the œsophagus. If unfavorable, Witzel's method should be done wherever it can be carried out.

6. Von Hacker's method should then be reserved for far-gone cases, and should, if the patient be very weak, be done under cocaine-anæsthesia, best at two sittings. If properly performed the outlook for making the fistula close tightly around the tube is good.

The remaining paper in this issue, "Bacteriological Investigations of Diphtheria in the United States," is contributed by Dr. William H. Welch, Professor of Pathology in the Johns Hopkins University. The paper is the report in behalf of the American Committee on Diphtheria to the Eighth International Congress of Hygiene and Demography, held in Budapest, September 1 to 9, 1894.

Insomnia of Old Age.

Dr. J. W. Dale, in the *University Medical Magazine*, recommends very highly the use of morphia with a small amount of Dover's powder for the relief of the sleeplessness which is frequently one of the most serious complaints of the aged. The ordinary hypnotics, such as the bromides, chloral, and the numerous coal-tar derivatives, answer well for temporary purposes, but not where the demand is long continued. Dr. Dale gives at first from the 24th to the 12th of a grain of morphine, with 2 or 3 grains of the Dover's powder. This amount will need to be increased slightly as the patient becomes accustomed to it, but the doctor has found that even after a number of years, patients do not require an increase beyond a ¼ of a grain of morphine and 10 grains of the Dover's powder. Its use, he has found, is best limited to persons over 70 years of age, at which time of life its regular use is tolerated with impunity, and he has never found it to do any injury. The object in using the Dover's powder is to increase the bulk of the medicine, so that the patient will not be apt to increase the dose. Any particular increase would result in nausea from the presence of the ipecac. In addition to this, the small amount of ipecac present tends to maintain healthy action of the skin, and stimulate the stomach and the functional activity of the liver, as well as to diminish the tendency to constipation.—*Massachusetts Med. Journal.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Microbic Origin of Purulent Surgical Infection.

MM. S. Arboing and E. Chantre, after reciting their views at length, sum them up as follows: The essential agents of purulent surgical infection are the ordinary microbes of suppuration. Should other microbes be present in the lesion with any frequency they are to be regarded in the light of complications, and not as necessary factors in the development of the purulent infection. A purulent infection can only result when the streptococcus (the authors confine themselves to that form) is endowed with the same virulence as it possesses in the acute and severe forms of puerperal septicæmia, and not with that which it exhibits in single phlegmon or erysipelas.

Though etiological relations between purulent infection, puerperal septicæmia and erysipelas may be suspected, yet it cannot be proved where and how the change in the pathogenic properties in the streptococcus, productive of different chemical conditions, is effected.—*Journal of the Royal Microscopical Society.*

The Treatment of Pruritus Vulvæ.

1. If diabetic, try specific treatment and diet, with warm lotions locally.

2. If connected with a chronic eczema of the genital organs, a gonorrhœal vaginitis, a chronic vaginitis with leucorrhœal discharge or vaginismus (with hysterical symptoms), suppress all exciting diets. If there is abundant discharge, inject night and morning 3-4 pints warm (45° C.) permanganate of potash solution (1 : 1000). Use three times a day the following lotion:

℞ Water.....	450	00	grams or parts
Alcohol.....	50	00	"
Mercuric chloride.....	1	00	"
Indigo carmine.....	0	05	"

If burning or itching come on (especially during second half of night) wash with water as hot as possible. Abstain from all pomades, ointments, etc., which by their fermentation, etc., increase the irritation.—*Medical Chronicle.*

Generalized Pneumococcus Infection.

M. Netter, at a meeting of the Society of the Hospitals, said that he had lately seen a generalized infection, including endocarditis, produced by pneumococcus. The patient, who was a youth of 19 years, had a very high fever, with pulmonary infarcts, and a cardiac murmur. The manifestations disappeared with the exception of the murmur, indicating that a permanent valvular lesion remained. Making a bacteriological examination of the blood and sputum, M. Netter found only the pneumococcus. In an abscess of the leg, developing upon the site of an erectile tumor, he had also discovered the same organism. In this case the microbe had not penetrated into the blood through the respiratory passages, but by way of the abscess just mentioned, and which was the first of all developments. This observation shows, furthermore, what had been already stated by M. Jaccoud and the speaker, that pneumococcus endocarditis is comparatively benign.—*La Tribune Medicale.*

Extraordinary Temperature.

M. Ch. Richet, at a recent meeting of the Biological Society, called attention to a remarkable case of hyperpyrexia observed in Sicily. The patient was a woman suffering from intermittent fever. While the morning temperature was no higher than 39° C. (102° F.), in the evening it ascended to 45° C. (113° F.), as observed by Professor Caparelli, of Catania. Upon two different occasions it even rose to 46° C. (114.8° F.). The utmost care was taken to avoid deception. Moreover, under the influence of quinine the temperature fell to 36° C. (96.8° F.). When the drug was suspended the mercury rose to 46° C. After a fresh exacerbation of longer continuance the temperature fell to normal and the patient recovered.—*La Medecine Moderne.*

Heart Disease.

Pawinski (*Therapeutische Monatscheft*) compares caffein natrio-salicylate with strophanthus and digitalis as follows:

In valvular diseases of the heart, with disturbance of compensation, digitalis and strophanthus are superior to caffein, but the latter can often do good service when the former are contraindicated.

In respect to regulating the heart rhythm, caffein is also inferior to the others; but in respect to excitation of diuresis, it is much superior. The best field for the administration of caffein is in diseases of the heart muscle, either functional or degenerative, and especially in the early stages of the disease. But in the later stages, when the heart, in consequence of progressive degeneration of the muscle fibers, is not able to perform its duty, and there are œdema, dyspnœa, and dilatation, then we must resort to digitalis.

Caffein is also indicated in acute insufficiency in patients whose circulatory system is otherwise healthy, such as after severe mental strain, moral commotion, and especially during fevers In many cases also caffein produces a pleasant narcotic effect.—*Canadian Practitioner.*

Treatment of Sunstroke.

The conditions of sunstroke are an immoderate heating of the blood, and, consequently, of the whole body. The heat stimulates the heart ganglia, and, through these, the heart muscle, which is already overworked, and paralysis of the heart, from exhaustion, follows. The immoderate heat also irritates the various nerve centers of the brain, and thus produces general convulsions, etc.

Koerfer (*Therapeutische Monatscheft*) prescribes prolonged chloroform narcosis to reduce the irritability of the heart ganglia and nerve centers, and then the ordinary therapeutic measures; *e. g.*, cool baths, large amount of fluids (per anum, if necessary), ether and camphor injections, etc Hirschfeld recommends, instead of the cold bath, a prolonged warm bath, the temperature of which is very slowly lowered, and venesection, if there be œdema of lungs or brain.—*Canadian Practitioner.*

Heart Disease and Menstruation.

Dr. Gow recently read a paper (*Lancet*) before the Obstetrical Society of London, with a record of 50 cases. In 28 the flow was unaltered; in 17 the flow was absent or scantier than before; in 5 the flow was either more profuse or recurred more frequently than before; in no case was there good evidence that heart disease gave rise to severe menorrhagia. It would seem that either amenorrhœa or scanty menstruation was a far more common accompaniment of heart disease than menorrhagia. A further analysis of these cases seemed to point to the fact that heart disease led to relative sterility, and also that it greatly increased the tendency to premature expulsion of the ovum. In conclusion, it was pointed out that a large number of women suffering from valvular disease of the heart pass safely through the period of pregnancy and labor. The cases were futher analyzed as follows:

1. Mitral stenosis (22 cases): In 9 cases menstruation was regular and the amount lost unaltered, in 5 cases menstruation was regular but more scanty, in 4 cases there was amenorrhœa, and in 4 cases menstruation was either more frequent or more profuse.

2. Mitral incompetence (15 cases): In 10 cases menstruation was unaltered, in 4 cases menstruation was more scanty, and in 1 case there was amenorrhœa.

3. Mitral stenosis and incompetence (7 cases): In 4 cases menstruation was unaltered, in 1 case menstruation was more scanty, in 1 case there was amenorrhœa, and in 1 case there was slightly increased menstrual loss.

4. Aortic incompetence and obstruction (2 cases): In both cases menstruation was unaltered.

5. Aortic and mitral incompetence (3 cases): In all cases menstruation was unaltered.

6. Aortic incompetence and obstruction and mitral incompetence (1 case): Menstrual loss was more scanty than before.—*The Kansas Medical Journal.*

Compound Tincture of Coal-Tar.

In the *American Journal of the Medical Sciences* Duhring writes a paper on compound tincture of coal-tar.

Summing up the result of his investigations, we may conclude—

1. That the best tincture of coal-tar is made with the aid of tincture of quillaia.

2. That the strength of the tincture of quillaia should be 1 to 4, with 95 per cent. alcohol.

3. That the coal-tar (1 part) should be digested with the tincture of quillaia (6 parts), with frequent agitation, for not less than eight days, and preferably for a longer period, and finally filtered.

4. The resultant product is a brown-black, clear tincture, which, upon the addition of water, forms a cleanly yellowish emulsion, the color and certain other characters varying with the kind of coal-tar employed.

5. The tincture is stimulating and is prescribed usually largely diluted, with from 10 to 60 parts of water, as a wash, and is useful where tar is indicated, as in certain forms of eczema, psoriasis, pruritus, and other inflammatory diseases of the skin. It is often more useful when employed weak than strong.

6. This preparation, which may be designated as "compound tincture of coal-tar," takes the place of several similarly composed proprietary preparations, known as "liquor carbonis detergens" and "coal-tar saponine."—*Therapeutic Gazette.*

Nephritis in its Surgical Aspects.

Dr. E. L. Keyes (*American Journal of the Medical Sciences*) says:

Healthy urine is sterile.

Purulent urine is always microbic.

Microbic infection takes place from within the body by a number of methods in the course of disease; it is often brought about by instrumental maneuvers on the part of the surgeon

A healthy organism and vigorous bladder may cope successfully with microbic invasion, and rid itself spontaneously, or with a little acid, of all damage arising therefrom—showing little or no inflammatory response.

A suitable condition of the patient's soil is essential to the propagation and perpetuation of inflammatory phenomena upon the urinary tract—after microbic invasion.

This condition, intensified by traumatism and physical weakness, notably of degenerative variety, is most intense where there is vesical distention with atomy, and when the ureters are dilated and the kidneys involved in the changes incident to tension below—namely, atrophy and sclerosis above, with or without surface catarrh.

Under these circumstances surgical pyelonephritis is most likely to declare itself as a result of microbic infection from below (occasionally from above)—in the course of suppurative disease or after operative interference.

Asepsis, antisepsis, and sterilization of urine are ends to be aimed at in genito-urinary surgery—but, like all other greatest goods, not yet attained in perfection. Much, however,

can be done by local means in a prophylactic and curative way, little by internal medication, and possibly as much or more than by any other means by flushing the urinary passages with natural mineral waters.—*American Lancet.*

The Forms of Diabetes.

Dr. George Harley gives the following classification of diabetes:

1. Hepatic diabetes—including the gouty variety.
2. Cerebral diabetes—including all cases of saccharine urine arising from nerve derangements.
3. Pancreatic diabetes—the most deadly form of the disease.
4. Hereditary diabetes—a form by no means uncommon, and one, too, where both brothers and sisters may labor under the disease without either their maternal or paternal parent having been affected by diabetes, though more distant members of the family may have suffered from it.
5. Food diabetes—including all forms of saccharine urine arising from the ingestion of unwholesome substance.

In the matter of treatment, besides diet and opium or codeine, Dr. Harley recommends croton chloral, strychnine, phosphoric acid for thirst, and an absolute prohibition of alcohol.—*Med. Record.*

The Administration of Sodium Salicylate in Rheumatism.

In Ziemssen's clinic the salicylate of soda is given per rectum in cases where it is not well borne by the stomach, or from any cause administration per os is contraindicated. When necessary, the rectum is first cleared out, and then, by means of a 7-inch sound, a solution of 6 to 8 grams natrio-salicylate in 100 c.cm. of water, to which 1½ grams tr. opii is added, is injected. The results are excellent.

Ruel recommends, in such cases, the local application of acid salicyl., and claims as good results as when administered internally. The following salve may be used twice a day, and covered over with oiled silk or any impermeable stuff: Acid salicyl., 10 to 30 grams; alcohol abs., 100; ol. Riemi, 200; chloroform, 10 to 15. Bourget also found the external application of salicylic acid to the affected joint very effective, and recommends it very highly. He applies an ointment similar to the above, and combines with it the internal administration of 1 to 2 grams of salacetol daily.

Salacetol is a new salicylic preparation, which is highly recommended as an intestinal antiseptic.—*Therapeutische Monatscheft.*

Concurrent Infections in Pulmonary Tuberculosis.

Prudden (N. Y. *Med. Jour.*), in a series of experimental studies on rabbits, found that animals subjected to concurrent infections with the tubercle bacillus and the streptococcus pyogenes showed a most remarkable formation of lung cavities. He thinks the view that tuberculosis of the lungs is liable to assume the character of a mixed infection by the entrance of other germs than the tubercle bacillus very important.

This conception of pulmonary tuberculosis serves to explain in the clearest way the varying vicissitudes of this disease, and the unfavorable course which it is liable to pursue when its victims are exposed to the widespread chances of infection with pyogenic germs in cities, and especially in crowded and improperly cleaned hospital wards. On the other hand, some, at least, of the beneficial effects of life in the open air of salubrious regions are explained; and the rationale of some of the favorable effects of so-called antiseptic treatment becomes clearer from this new point of view. But, beyond all, this conception of phthisis emphasizes the importance of definite and intelligent measures for warding off the complicating lesions by scrupulous attention to hygiene and sanitation, and especially the avoidance, in ways suggested by our modern notions of cleanliness, of common sources of aerial infection.

Sero-Therapy in Tetanus.

Remesoff and Fedoroff recently reported in the *Centralblatt fur Bakteriologie*, a case of tetanus treated successfully by means of the serum of an immunized animal. The serum used was estimated to have the curative value of 1-300,000. The symptoms of the disease were already marked when the first injection of 50 c.cm. was made. The serum was obtained from a dog which had been rendered immune to tetanus. The next day after the first injection the patient was already improved, and the improvement continued until the fourteenth day, when he was discharged well.

The authors summarize the facts which have been developed by experience with this method, up to the present time, as follows:

1. The duration of this disorder is decidedly diminished by sero-therapy.
2. The temperature is reduced.
3. Sleep is restored.
4. The attacks of spasm grow less severe and more infrequent.
5. The frequency of the pulse is diminished.
6. Great improvement in the general condition is induced.

The Treatment of Erysipelas.

The subject of the treatment of erysipelas naturally falls into the (1) dietetic, (2) constitutional and (3) local, says Dr. J. M. Anders in the *Therapeutic Gazette.* The following summary shows in a few words the proper treatment of this disease:

1. Proper attention to the diet is of paramount importance.

2. Stimulants are rarely necessary if the dietetic requirements are fully satisfied, but may be freely exhibited when indicated.

3. Of drugs, iron has been widely tested and found to be of great value, though it matters little which salt or preparation is employed.

4. Quinine, when administered with iron, reduces the temperature, supporting at the same time the vital functions.

5. The use of antiseptics *per os* is to be recommended.

6. Pilocarpus is in a small proportion of cases powerful to abort the affection. To reduce temperature merely, pilocarpus should be employed in intense pyrexia, particularly where the favorable morning remisssions do not occur.

7. The question of the local treatment of erysipelas has not as yet been set at rest, but agents intended to exclude the air and such as possess a germicidal power, especially corrosive sublimate, are highly useful.

8. That the erysipelococcus of Fehleisen, which is found chiefly in the more superficial channels of the corium, may be attacked directly by the corrosive-sublimate solution when the latter is used after scarification, is quite probable.

9. In erysipelas migrans, the germicide should be injected beneath the skin, just beyond the edge of the part inflamed.

Boracic Acid in Constipation.

Excellent results may be obtained in many cases of constipation by the application of powdered boracic acid to the rectal mucous membrane The writer's mode of application is as follows:

The ordinary rectal speculum having been introduced, half a drachm of powdered boracic acid, either pure or mixed with an equal quantity of starch, is introduced by means of a small spatula; a soft mass of cotton is then grasped by a pair of dressing forceps and used as a plunger to carry the boracic acid into the bowel. Applications of this sort will often secure an evacuation of the bowels in the course of an hour or two. The best time for the application is before breakfast. The applications are also useful made in the afternoon or evening, especially in very chronic cases. Cases in which this method is found most useful are those in which constipation is due to loss of sensibility in the nerves of the rectum, in consequence of impairment of the normal reflexes by which nature calls for an evacuation of the bowels.

This remedy will be found very valuable in cases of leucorrhœa of the rectum. In cases in which irritability exists, the boracic acid must be mixed with twice the quantity of powdered starch, or an equal quantity of subcarbonate of bismuth.—*Mod. Medicine.*

A New Parasite in America.

The announcement of the discovery in this country of the "Distoma Ringeri," by Prof. Ward, of the University of Nebraska, is attracting more attention abroad than at home. This fluke has hitherto been found only in the far East—China, Japan, Corea and Formosa—where it infests the lungs of man, giving rise to periodical hemoptysis (Foster's Med. Dict.) and chronic cough with rusty mucoid expectoration. Already we are told that if this parasite "is now endemic in America we may expect to hear more about it soon, not only as a parasite of the lower animals but as a cause of endemic hemoptysis in man." Here is a brilliant opportunity for the men who are "in love with a microscope" and prone to "flirt with pathologic specimens." Endemic hemoptysis may soon become as fashionable as appendicitis.—*Jour. of the Amer. Med. Ass'n.*

A NEW invention called the thermogen is now being tried in several of the English hospitals with marked success. The object is to sustain the heat at a uniform temperature when artificial means are required, and of course its use would be limited to hospitals or institutions where the necessary facilities are easily obtainable. The thermogen consists of a light quilt containing a coil of wire bent in the form of a gridiron, inclosed in insulating and non-conducting material, and imbedded in cotton, wool or other soft substance, with a silk or woolen covering. The heat is produced by the resistance of the coil to the flow through it of the electric current. A uniform temperature of about 150° can be maintained for any length of time, the heat being prevented from going above that by the melting of a fuse which instantly shuts off the current. In those houses lighted by electricity the quilt can be connected with the ordinary incandescent terminals, but the principal use of the quilt would be confined mostly to hospitals, during lengthened operations, or in those attended with hemorrhage. —*Ed. N. Y. Med. Times.*

Untoward Effects of Quinine.

Dr. J. Schenck of Carmel, Ill., cites (*Jour. Amer. Med. Assoc.*) instances in which quinine produces a herpetic eruption on the lip, ear, cheek or prepuce. He also reports a case where five grains produce acute coryza. In an elderly woman ten grains during half a day will produce large, reddish-purple blotches on the ulnar margin of the left hand, and another, about the size of a half-dollar, on the upper portion of the left concha; the eruption is accompanied by a hot tingling sensation, and disappears during the following twenty-four hours after the remedy has been given; the same train of symptoms invariably occur after quinine. In another case twenty grains, given in four-grain doses two hours apart, invariably produces a similarly colored condition of the skin, on the back of the left thumb, between the first and second joints. The burning sensation is very severe, the epidermis is raised into a blister and afterward shed. In another patient twenty grains will cause the mucous mem-

brane covering the glans penis to change to a dark purple color, accompanied by intense itching, followed by the shedding of the epithelial layer in the course of the following week. In a fourth case four grains will cause a most annoying itching of the glans penis in from thirty to sixty minutes after it has been taken. If taken at bedtime the itching will continue until morning. The party is about fifty years old, and during the last eight or ten years of his life this effect has invariably followed the use of quinine, while previous to that time this effect was not noticed, although he has taken quinine frequently since early childhood.—*Medical Standard.*

SURGERY.

The Cause and Prevention of Neuralgia in Amputation Stumps.

Witzel (*Centralbl. f. Chir.*) holds that neuralgia after amputation is not caused, as is generally supposed, by the formation of neuromata at the ends of the divided nerves. He states that if such were the case it would be necessary to lay aside the amputating knife. The neuralgic pains, he believes, are due to adhesion of the neuromatous swelling to the end of a bone. In order that its functions may be properly performed a nerve should move freely in its sheath. The structural elements which serve the special functions of a nerve are during life extremely delicate and almost fluid. The ordinary movements, therefore, of an adjacent joint would interfere with the structure and functions of the nerves of a limb if these nerves had no longer free range of movement in the direction of their long axes. In two cases of neuralgia after amputation in which Witzel had opportunities of dissecting the stumps he found thick neuromatous swellings at the ends of the divided nerves, which were bound down by tough cicatricial tissue to the ends of the bones. It is evident that during movements of the stump at the nearest joint the fixed nerves must be stretched, those on the flexion side during extension and those on the extension side during flexion. In neuralgia caused by confinement of a nerve in a mass of callus the pain, it is held, is due to the prevention of the nerve's movement and not to its compression. As a preventive treatment Witzel recommends that in every amputation as much attention should be paid to the nerves as to the large arteries, and that the former should be pulled away from the flaps and divided high up. Attention should be particularly directed to this precaution in cases of amputation at the ankle and shoulder.—*Epitome, British Medical Journal.*

Deformities in Knee-Joint Disease.

Dr. A. M. Phelps contributes an article to the New York *Medical Record* on the etiology of the deformities occurring in knee joint disease, in which he carefully reviews the old theories of deformity and concludes that typical deformities are produced by change of leverage and action of muscles due to:

1. A voluntary effort to relieve pressure and pain.
2. Involuntary spasm and contraction of muscles, which increases the deformity by advantage of leverage due to flexion.
3. Nervous irritation of groups of muscles due to localized lesion in or about the joint.
4. Exceptional deformities are produced by pathological destruction of bone or soft parts.
5. Outward rotation of the leg is produced by spasmodic contraction of the biceps after flexion has taken place. Flexion allows lateral and rotary motion at the joint.

The Use of the Catheter After Labor.

Recht (*Journ. de Medecine et de Chirurgie Practiques*) shows that on the evidence of repeated observations micturition is almost always spontaneous. In 6,666 labors under Pinard's care in the course of the last four years, the catheter has been used only twenty times, and in the 1,920 labors last year only three times. Pinard objects very strongly to routine use of the catheter, which even in skilled hands often sets up cystitis. The practice in Paris lying-in hospitals is, however, very varied. At the school of midwives nearly every newly delivered patient has the catheter passed. Maygrier, at the Pitie, delays the use of that instrument until twelve hours have elapsed after labor without the patient being able to pass water voluntarily. Bar allows a maximum of eighteen hours; Parak and Budin, twenty-four; Tarnier, thirty-six; Champetier de Ribes, forty-eight. Ribemont Dessaigues, at the Hopital Beaujon, objects to the catheter as strongly as Pinard. Boissard finds that not only is there danger of cystitis when the catheter is passed after labor, but the patient is liable to lose the power of voluntary micturition for many days through nervousness.—*British Medical Journal.*

Senile Osteomalacia of the Coccyx, Sacrum and Spinal Column.

At a meeting of the Society of Practical Medicine and Surgery M. Reliquet gave the history of a case which had given rise to the most varied diagnoses. It related to a man who died at the age of 70, and whose autopsy failed to show the presence, in any portion of the tissues examined, of the least nodule of cancer or tubercle. The coccyx, sacrum, and the part of the left ilium adjacent to the sacrum, the last lumbar vertebra, and the other lumbar and dorsal vertebræ presented the unmistakable aspect of localized senile osteomalacia (softening of the osseous tissue, engorgement of areas by black blood, disappearance of the sacro-coccygeal articulation, etc.). In the commencement of the affection the patient had presented all the symptoms of sacro-coccygeal arthritis, with spontaneous pains, localized in the coccyx, and transitory congestions of the rectum and prostate, the

latter of which symptoms had occasioned the diagnosis, by a surgeon, of cancer of the prostate. The duration of the first stage was six months. The second period was a little longer and was marked by the invasion of the sacrum and the left side of the ilium. From this time the pain extended over all the surface of the sacrum and at the same time a considerable œdema occurred, at first confined to the side of the sacrum, subsequently spreading to the buttocks, and finally invading the entire left lower limb. A vague sensation of fluctuation communicated to the touch, joined to the above signs, excited the suspicion of an abscess situated at the sacro-coccygeal joint. Nevertheless, the patient entered a third and final stage, characterized by a lateral S-shaped curve of the vertebral column and the development of cerebral disorders, such as disorderly movements of the face and jaws, incoherence of language, etc. At the same time the pain became intolerable, the œdema extended to the hips, the buttocks, and both lower limbs, the urine became purulent, and the man finally died in a state of coma.—*Le Progres Medical.*

Chloroform Anæsthesia Without Danger.

Dr. G. Maurange recommends the subcutaneous injection of the following solution as a preparatory and prophylactic measure before administering chloroform:

℞ Neutral sulphate sparteine..... grs. ivss.
Muriate morphine..... grs. jss.
Sterilized water.....ad., ʒijss.

Inject 1 cem. of this solution a quarter of an hour before administering the anæsthetic.

Out of one hundred and six operations where chloroform was employed with preliminary injection of this cardiac stimulant, not a single disagreeable symptom was observed, however long the subject was under the anæsthetic. The period of excitement was suppressed and the absorption of the anæsthetic was reduced to a minimum on account of the morphine.—*Cin. Lancet.*

Aseptic Vaccination.

Graff (*Northwestern Lancet*) urges that the bad effects alleged of vaccination are chiefly possible by failure to make the operation aseptic. He thinks all such risks may be avoided. He employs sterilized lymph in a sealed glass tube. The skin is thoroughly washed and rubbed with a two per cent. solution of lysol and dried. The old-fashioned lancet is disinfected by boiling or with the same solution, care being taken to remove all traces of the disinfectant. The tube is then opened and a drop of virus placed on the point of the lancet, with which he makes three slight "picures" just through the epidermis about one inch apart. Finally the space is covered with gauze or absorbent cotton, secured in place by a roller bandage or rubber adhesive bandage. The dressing is not to be removed for three weeks, or if accidentally displaced it is to be renewed. By this method he obtains typical vesicles with little redness and no fever, swelling or pain; the only inconvenience being a little itching. The contents of one tube will do for five to seven vaccinations, but these must be done at once, since after opening it will not remain aseptic.—*Phila. Polyclinic.*

Abortive Treatment of Gonorrhœa by Permanganate of Potash.

Large injections of permanganate of potash methodically used is the best method of treatment yet introduced. Its advantages are: being absolutely painless in cases of anterior urethritis, and scarcely painful in cases of inflammation of the whole tract; it can be commenced or left off without inconvenience; it has no detrimental action on the mucous membrane, but suppresses every trace of discharge from the first lavage, and is successful about eleven times out of fifteen. The size of the injection, and its frequency and strength, must be adapted to individual cases. Generally strengths of 1 to 4,000, or 1 to 2,000, or even 1 to 1,000 are tolerated.—*Revue de Therap. Med.-Chir.*

Dr. Gordon Sharp (Leeds), for the prevention and treatment of chapped hands, and as an antiseptic and deodorizer for the hands, advises:

℞ Spir. of camphor,
Spir. of nitrous ether,
Strong acetic acid..... āā part j.
Mix and add:

℞ Glycerine..... parts xiij.

Wash the parts with warm water; dry, and rub in the liniment at bedtime. The application dries in a few minutes. It may be applied again in the morning and washed off in a few minutes. Owing to the production of acetic ether the application has an agreeable odor.—*British Medical Journal.*

Diet in Severe Forms of Diabetes.

Schmitz (*Deutsche Med. Wochenshrift*) insists that in the severe forms of diabetes, when the patients are much reduced and the proportion of sugar in the urine continues to be high in spite of exclusive albuminoid and fat diet, it is better to almost exclude meat from the diet list and give in its place more fat and a moderate amount of carbohydrates. He gives several histories of cases where the patients had been reduced to mere skeletons on the ordinary anti-diabetic diet. This had at first helped, but latter had failed altogether to keep down the high per cent. of sugar in the urine. By giving much less albumen and more starch and fat, the amonnt of sugar in the urine was in a few weeks reduced from 5 per cent. and more to less than 1 per cent. in some cases with decided improvement in general health.

Treatment of Gonorrhœa.

Dr. Da Costa treats acute gonorrhœa by spraying the canal with a 15-volume solution of hydrogen peroxide, then applying an antiseptic solution consisting of oil of cinnamon dissolved in liquid vaseline, beginning with a one-drop-to-the-ounce solution for the first day, and afterward using a three-drops-to-the-ounce solution.

Diday recommends a five-per-cent. solution of nitrate of silver. The urethra is compressed at the posterior part, and the anterior portion of the urethra is filled and distended by the injection. Six out of eight cases were cured in ten days.

Janet employs a solution of permanganate of potash introduced by means of a siphon, affording sufficient pressure to carry the solution into the bladder. The solution should be used warm and immediately after urination. It should be encouraged to enter the bladder by having the patient make efforts at emptying the bladder while the injection is being made, the orifice of the urethra being compressed around the nozzle of the siphon so as to prevent the escape of the liquid. The more intense the inflammation, the weaker the solution should be. In severe cases the proper strength is 1–4000; in moderately severe cases, 1–2000; if acute inflammatory symptoms are absent, 1–1000. A weak solution employed slowly, so that it is retained for some time in contact with the mucous membrane, produces the same effect as a strong solution employed for a shorter time. In severe cases an injection should be made once in four hours; in subacute inflammation, once a day, or once in two days. A whitish secretion occurs a few hours after the injection, then the surface becomes dry. Ten or twelve irrigations are usually required to effect a cure.—*Modern Medicine.*

Ichthyol in Gonorrhœa.

One of the latest uses suggested for ichthyol is the treatment of gonorrhœa, for which it is employed in injections of a 2–5 per cent. solution. It is also used for primary and secondary catarrh of the bladder in a ½–1 per cent. solution. The advantages claimed for it are:

1. A rapid cure of simple gonorrhœa through the destruction of the specific organisms.
2. An antiphlogistic and resolvent effect.
3. The prevention of stricture.
4. The painlessness of the application, and the relief of pain when present.
5. In the treatment of catarrh of the bladder, the destruction of germs, the prevention of ammoniacal fermentation, and the relief of a catarrhal condition of the mucous membrane.—*Modern Medicine.*

Strontium Lactate as a Diuretic.

Dr. A. Ried (*Therap. Blatter*), from his extensive experience with strontium lactate in Bright's disease and other dropsical affections, arrives at the following conclusions:

1. In many cases of Bright's disease strontium lactate diminishes the proportion of albumin in the urine to a considerable degree; this does not apply in cases of contracted kidney.
2. The administration of the strontium salt in the form of powders frequently gives rise to nausea and vomiting; the remedy should therefore be given only in solution (3 to 4 tablespoonfuls of a 1:6 aqueous solution daily).
3. Strontium lactate, thus administered, acts decidedly as a diuretic.
4. Strontium lactate may be recommended, owing to its diuretic properties, in pleuritic exudations, as a temporary substitute for the salicylates—salicylic acid or its compounds, when given for some length of time, may produce toxic effects, while the strontium is well tolerated even for weeks.—*Amer. Medico-Surg. Bulletin.*

Epididymitis.

Rollet (*Medical Press and Circular*) holds that when epididymitis occurs as a complication of gonorrhœa, irrigation of the entire urethra should not be intermitted, since otherwise there is danger of the second testicle becoming involved. The best treatment, in his opinion, is salicylate of sodium, a drachm and a half daily, or tincture of pulsatilla, 10 drops three times daily. The action of this agent is not as constant as that first named. Refrigeration is the best means of allaying pain; this is produced either by application of ice to the inflamed parts or by the spray of chloride of ethyl. The latter must be used with caution, on account of the sensitiveness of skin of scrotum. Reclus recommends the application of compresses of warm water. Rollet has been using for some time back, with considerable satisfaction, guaiacol, which he applies by means of a brush over the surface daily; not more than 1 gramme, or 20 drops, is used each time. The pain produced by the agent is slight and of short duration, while that appertaining to the malady disappears in about two hours, and the temperature falls.—*Therapeutic Gazette.*

Report of the Collective Investigation Committee on Anæsthesia at the Recent Surgical Congress in Berlin.

Professor Gurlt, Berlin, in presenting the report of the committee on anæsthesia, said that, on the proposition of the society, he had carried out the investigation to a fourth year. In 1893, 63 reports had been received, of which 9 were from abroad. Fifteen reports had been sent from 21 German university clinics. The total of last year's cases was 51,846. Of these, 32,723 were chloroform administrations, 11,617 of ether, 3,896 with ether and chloroform, 750 with chloroform, ether, and alcohol (Billroth's mixture), 2,769 with bromide of ethyl, 91 with nitrous oxide. The total fatalities were 20, and of these, 17 were due to chloroform. The average death-rate was 1 in 2,587 administrations. The death-rate from chloroform was 1 in 1,924.

When the results of the previous year were added, the totals were 163,493 administrations, with 61 deaths. The rate of mortality was: Chloroform, 1 in 2,655; chloroform and ether, 1 in 8,014; Billroth's mixture, 1 in 26,268. In fact, only 1 death had occurred from ether narcosis, and that was a case of heart disease. In correspondence with the low death-rate from ether, its employment had largely increased of late years, from 6,200 in 1892 to 11,600 in 1893. Pichet's purified ice chloroform had been used 3,890 times, with 2 deaths, so it would appear that the dangers of chloroform inhalation did not lie in any accidental impurity; indeed, the facts seemed to point the other way, and that the danger was directly proportionate to the purity of the chloroform. This consideration had lately led to a different mode of administration. It had been given more slowly, and occasionally atropine and cocaine had been used with it. As regarded accidents, 255 severe cases of asphyxia had occurred, and tracheotomy had to be performed three times. Konig's cardiac massage, so called, was frequently used, but not always with success. Ether had, therefore, shown itself the least dangerous anæsthesia, ten times less dangerous than chloroform, but it was not without its shady side: it was dangerous in lung affections. It was agreed to still continue the investigation.—*Therapeutic Gazette.*

Hot Bichloride Poultice.

Rogers (*Northwestern Lancet*) warmly commends, in the treatment of variously assorted septic conditions, bichloride poultice after incision and for drainage. Where this is necessary, the affected part is splinted and is completely enveloped in hot bichloride gauze, or cloths wrung in a hot 1 to 3,000 bichloride solution. Over this is placed a thick layer of absorbent cotton wrung out in the same solution. The whole is entirely covered by a pad of oiled silk, retained in position by a roller bandage. He holds that wherever the ancient flaxseed poultice is indicated, the bichloride can be substituted with eminently more satisfactory results.—*Therapeutic Gazette.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM SEPTEMBER 23, 1894, TO OCTOBER 6, 1894.

First Lieutenant Benjamin Brooke, Assistant Surgeon, is relieved from duty at Camp Pilot Butte, Wyoming, and ordered to Fort Canby, Washington, for duty.

First Lieutenant Thomas W. Raymond, Assistant Surgeon, is relieved from duty at Fort Canby, Washington, and ordered to Fort Riley, Kansas, for duty.

Capt. John L. Phillips, Assistant Surgeon, ordered to report in person to commanding officer Fort Walla Walla, Washington, for duty at that station, the assignment to duty at Fort McKinney, Wyoming, being revoked.

Leave of absence for two months and fifteen days, to take effect on being relieved from duty in the Department of Texas, is granted Capt. William B. Davis, Assistant Surgeon.

Leave of absence for one month is granted Capt. Adrian S. Polhemus, Assistant Surgeon, with permission to apply to the proper authority for an extension of fourteen days.

The extension of leave of absence on surgeon's certificate of disability granted Lieutenant-Colonel Joseph R. Gibson, Deputy Surgeon-General, is further extended six months on account of sickness.

NEWS AND MISCELLANY.

Mississippi Valley Medical Association.

The twentieth annual meeting of this well-known organization will be held, as previously announced, at Hot Springs, Ark., November 20, 21, 22 and 23, 1894.

The general committee of arrangements held their final meeting on September 1st, in the city of St. Louis, there being present, in addition to the committee, President Scott, of Cleveland; Vice-President Strauss, of St. Louis; and Secretary Woodburn, of Indianapolis. Dr. T. E. Holland, of Hot Springs, presided. All of the preliminary arrangements for the meeting of the association were completed.

Owing to the hearty cooperation of the railroads, the arrangements in this direction will surpass those of any previous meeting. On motion of Dr. I. N. Love, of St. Louis, a committee of five railroad officials was appointed to secure the desired reduction of rates. This committee consists of Messrs. Townsend, Crane, Snider, Wishard and Ives.

The interest and enthusiasm manifested in all parts of the country concerning the meeting in November are certainly remarkable. The fact that Hot Springs is to be the place of meeting will probably be an inducement for many to attend. From the large number of favorable responses to his preliminary announcement, the secretary feels justified, even thus early, in predicting an attendance double that of any previous meeting of the association.

Let every doctor who can possibly leave home for a few days go to Hot Springs in November. Let him take his family and his friends, and not only a profitable meeting, but a royal good time will reward him for the exertion.

FREDERICK C. WOODBURN,
Secretary.

ORIGINAL ARTICLES.

OLIVER WENDELL HOLMES, PHYSICIAN.

A. L. BENEDICT, A.M., M.D., Buffalo, N. Y.

It is not often that a member of our profession attains more than local eminence; still less frequently does a physician achieve immortality in literary or scientific pursuits without forfeiting his allegiance to the medical profession. In recalling the life of Oliver Wendell Holmes, it is not enough to say that he once studied medicine, that he was a doctor before he was a poet and an essayist. The best of his life is identified with medical teaching and medical practice. Even after retiring from the active pursuit of his calling he was none the less a doctor, none the less the professional brother of every honorable physician. He is the eloquent orator, the brilliant essayist, the quaint satirist, the kindly poet, not *from* but *of* the medical profession.

As a poet, he was one of a group of five or six bards of second rank who wrote no epic masterpieces and who fell short of the inspiration of Shakespeare, but who appeal to heart and soul as the few greater poets never have and never can. Longfellow, Bryant, Whittier, Lowell, Holmes, represent an era of American development. For many years contemporaries, each in his own style, yet all bearing the common imprint of the aspirations and energy of the New World, they have vindicated the charge that America had only the possibilities of materialistic advancement.

Few poets have been more optimistic than Holmes, few have appealed so generally to the sympathies of all classes. His jollity never descended to the comic, his humor has almost always a tinge of pathos, yet his sadness is never somber.

Every college man—even graduates from professional schools may be included—feels his heart grow warmer and his memory of class and fraternity bonds grow brighter as he reads Holmes' poems addressed to the "boys." The physician appreciates the satire and learns a useful lesson from the "Stethescope Song" and "Rip Van Winkle, M.D." Holmes might be called the poet of commemorative exercises, so many of his happiest strains having been prepared for anniversaries of historic events, for college commencements and reunions, for society meetings and banquets.

Many of Holmes' essays are classics of medical literature. The sound logic and entertaining satire of "Homœopathy and Its Kindred Delusions," the almost paternal kindness and practical wisdom of his "Address to the Young Practitioner" and of similar addresses to students are well worth reading and rereading. His address on "Scholastic and Bedside Teaching," delivered in 1867, anticipated by a generation the recent beginnings of a reform in clinical instruction. In this and other papers he urges the superiority of practical instruction and of actual relief of

human suffering over purely scientific methods; yet in the "Mechanism of Vital Action" and the "Mechanism of Thought and Morals" we have a glimpse of his firm grasp of philosophic principles. In the "Position and Prospects of the Medical Student" his humanity and chivalry burst forth in an eloquent protest against the brutal disregard of the feelings of the patient by a certain grade of students and surgeons and an appeal for the respect due the modesty of the humblest woman.

If Dr. Holmes had never visited a patient, never delivered an anatomical lecture, never attended a medical meeting, his claim to fellowship in the profession and the claim of the profession upon his genius would be insured by his pioneer work in regard to the etiology and prophylaxis of puerperal fever. He proved its contagiousness; he traced the infection from patient to patient, carried by midwife or physician from post mortem or dissecting-room to the lying-in chamber. After more than half a century we can add only the conception of puerperal fever as essentially a septicæmia or pyæmia and the value of chemical antisepsis.

There is a characteristic grim humor in the words in which Dr. Holmes fixes the blame of puerperal fever upon the careless physician or midwife: "It appears a singular coincidence that one man or woman should have ten, twenty or thirty cases of this rare disease following his or her footsteps with the keenness of a beagle through the streets and lanes of a crowded city, while the scores that follow the same paths on the same errands knew it only by name. . . . It is the practical inattention to similar coincidences which has given rise to the unpleasant, but often necessary, documents called indictments, which has sharpened a form of the cephalatome sometimes employed in the case of adults and adjusted that modification of the fillet which delivers the world of those who happen to be too much in the way while such striking coincidences are taking place."

It is also significant that while the bacterial etiology of the fever was not recognized, Dr. Holmes asserts in most unequivocal terms the existence of a material contagion and notes the causative relation of erysipelas: "Within the walls of lying-in hospitals there is often generated a miasm, *palpable* as the chlorine used to destroy it." Summing up several detailed reports, he says: "The evidence appears to me altogether satisfactory that some most fatal series of puerperal fever have been produced by an infection originating in the matter or effluvia of erysipelas." He concludes a most earnest plea for conscientious observance of precautions against communicating the disease with these words: "God forbid that any member of the profession to which she trusts her life, doubly precious at that eventful period, should hazard it negligently, unadvisedly or selfishly."

The rules laid down by Dr. Holmes for practical guidance of the obstetrician will bear requoting:

"1. A physician holding himself in readiness to attend cases of midwifery should never take any active part in the post-mortem examination of cases of puerperal fever.

"2. If a physician is present at such autopsies, he should use thorough ablution, change every article of dress and allow twenty-four hours or more to elapse before attending to any case of midwifery. It may be well to extend the same caution to cases of simple peritonitis. [It is altogether likely that *simple* here means non-puerperal rather than non-septic.]

"3. Similar precautions should be taken after the autopsy or surgical treatment of cases of erysipelas, if the physician is obliged to unite such offices with his obstetrical duties, which is in the highest degree inexpedient.

"4. On the occurrence of a single case of puerperal fever in his practice, the physician is bound to consider the next female he attends in labor, unless some weeks at least have elapsed, as in danger of being infected by him, and it is his duty to take every precaution to diminish her risk of disease and death.

"5. If within a short period two cases of puerperal fever happen close to each other, in the practice of the same physician, the disease not existing or prevailing in the neighborhood, he would do wisely to relinquish his obstetrical practice for at least one month, and endeavor to free himself by every available means from any noxious influence he may carry about with him.

"6. The occurrence of three or more closely connected cases in the practice of one individual, no others existing in the

neighborhood and no other sufficient cause being alleged for the coincidence, is *prima facie* evidence that he is the vehicle of contagion.

"7. It is the duty of the physician to take every precaution that the disease shall not be introduced by nurses or other assistants, by making proper inquiries concerning them and giving timely warning of every suspected source of danger.

"8. Whatever indulgence may be granted to those who have heretofore been the ignorant causes of so much misery, the time has come when the existence of a *private pestilence* in the sphere of a single physician should be looked upon, not as a misfortune, but as a crime; and in the knowledge of such occurrences, the duties of the practitioner to his profession should give way to his paramount obligations to society."

We are tempted to quote from each of the essays mentioned. The difficulty is not to find a passage brilliant enough to be taken from its context, but to select those which might be spared.

A peaceful death, without the pain of sickness, with only the gentle warning of old age, has finished a life of honor to his profession, of service to his country, of gratification to the thousands who have read his poems and essays and realized that they were happier and better from having come within touch of his benevolence and sympathy.

A CASE OF COMPOUND COMMINUTED FRACTURE OF THE SKULL WITH LACERATION OF THE MEMBRANES AND LOSS OF BRAIN SUBSTANCE.

J. B. CRANDALL, M.D., STERLING, ILL.

Edward Heady, single, aged 25, American, a farm laborer, was injured July 19, 1894. I was called by wire to the place of accident, some twenty miles southwest of Sterling, to see the case in consultation with Dr. A. C. Smith, of Tampico, Ill.

The nature of the accident to our patient, which occurred at about 6 o'clock P.M., was from some entanglement of the rope which was attached to the hay fork. While the line was in extreme tension while in the act of hoisting hay with the ordinary horse-power, it snapped asunder, the eye of the cast-iron pulley striking with great force the right side of the head, crushing in bones, membranes, and badly lacerating and pulverizing brain substance. The accident happened some five or six hours prior to my arrival. Dr. S. was present soon after the accident and had the hemorrhage checked, which was excessive upon his arrival. He also rallied him from the shock by the use of subcutaneous injections of spts. vini gallici. The conveniences for an operation and the light were poor.

We immediately put him under the influence of chloroform and gave him the benefit of aseptic dressings. The force of the blow was upon the right parietal bone some 1½ inches posterior from the middle of the coronal, suture and about the same distance from the greatest convexity of the right parietal bone. The opening into the bony vault was some 1¾ inches from anterior to posterior points, while the superior-inferior margins were some ¼ inch less.

There were several pieces of detached bone. The largest was oblong in shape, 1¼ inches by ¾ inch in size. Several smaller pieces were also torn and driven into the brain substance through the membranes.

The dura was badly lacerated from the edge of the anterior central convolution of cerebrum to the interparietal fissure, from which arose extensive hemorrhage that was controlled with iodoform gauze. We also had more or less trouble with superficial arteries of scalp that were retracted so that we had to surround them with a needled ligature.

After elevating and smoothing down the rough edges of the fractured skull

with chisel and bone forceps, we flushed out the wound, removing all of the *débris* of loose brain substance, with hot carbolized water, closed the wound with silk sutures, leaving an opening at the lower border for drainage packed with iodoform gauze.

Before the operation the patient appeared rational so far as intellect was concerned, but his left arm, forearm and hand were useless; and one of the first inquiries when he recovered from chloroform was to know if he could ever regain the use of his hand, as up to this time there had been no improvement in the use of his arm. Patient also complained of an unnatural sensation about the face like a person under the sting of a nettle. In looking for results we see that the areas correlated with facial movements are at the anterior part of the infracentral, while the arm areas are in the middle portions of the anterior and central gyrus. It was impossible to define the boundaries, but it was evident we were very near the line, which was a little anterior to the base of operation. We assured him, not without some doubts unexpressed, that time would eventually restore the use of his arm, and later we were pleased that our prognosis was correct.

After making a nice toilet for the head, the outer dressing being carbolated gauze, we ordered a small powder of pulv. opii. The after-treatment was alternative doses of Hg Cl and pulv. opii for the first ten days. There was paralysis of the bladder and partial paralysis of the bowels for a time. Dr. Smith, who had the after-treatment, told me he used the catheter for a week or more, and that he used injections for the bowels for the same length of time, but that they gradually assumed a normal condition.

He also lost the sense of taste for a time; that came to him after a period of two weeks. Sight and hearing were not affected. Sense of smelling partially lost for a short time.

There was also loss of power of legs as well as loss of power of body; not able to control movements by will power; faulty coördination owing to some disturbance, if not lesion of the cerebellum.

I have not seen the case since the night of injury, but Dr. Smith was kind enough to furnish the facts and all of the interesting features in the case since. At present, some two months after receipt of injury, our subject is up and able to perform light labor; has the use of all the special senses; also has the control of and is able to use his hand and arm. Not as strong as before accident, but it has been gradually returning to its normal condition for the last four weeks. He can see some improvement in strength each day. The wound in the head is practically healed; has overcome his anemic condition; general health good.

From the outlook at present Mr. Heady will be able to resume his ordinary farm labor in a few weeks.

Much praise is due Dr. Smith for the attention and judicious management in the case and after-treatment.

As the results are all we could ask, so far as surgical aid and medical attendance are able to restore, where all kinds of appliances are within reach and educated nurses are at our every call, I fail to see where we could have improved the conditions of our patient in this case.

I often think I would sooner take my chances with a surgeon with ordinary skill, with pure country air, than with an expert in the city hospital with city surroundings. A surgeon may make cuts, but after all it takes nature to heal them up again.

Epistaxis in Children.

M. Verneuil recently read a very interesting communication before the French Academy of Medicine upon the subject of epistaxis in children (*La Loire Mèdicale*). Prof. Verneuil holds that nosebleed in children is due, in a large number of cases, to hepatic disturbance of some sort, especially such conditions as are present in the rheumatic diathesis. He remarks as follows:

"The practice has been to stuff these pale, anæmic children with tonics of all sorts, but this treatment, by predisposing to congestions, is diametrically the opposite of the treatment required by these patients. That which is first of all necessary in these cases is the alkalines, a vegetarian regimen, and cold douches over the liver. This treatment, which I employed in the case of a young man of seventeen years, has given excellent results; the hemorrhages have disappeared."

COMMUNICATIONS.

TREATMENT OF OPEN OR COMPOUND FRACTURES.*

HENRY H. MUDD, M.D., St. Louis, Mo.

An open wound communicating with a fractured bone is a serious complication. Every effort is directed to its closure by sound healing. Its importance and the difficulty of its management is determined largely by the amount of injury inflicted upon the soft tissues about the fracture, and by the extent of the comminution of the bone. This open wound is usually determined by the violence which inflicts the fracture, but may result from ulceration. An oblique fracture where the skin has been torn by the sharp angling of the bone, with or without impact against an external object, offers a good opportunity to convert a compound into a simple fracture.

Fractures by direct violence which is not crushing, even if the bone is comminuted, present often good opportunity for the immediate closure of the wound. The soft parts are not necessarily much injured by such a fracture. This is especially true where the bone is superficial.

Extensive lacerations and contusions of the soft parts with a small or a large wound of the skin preclude an effort at immediate closure of the skin wound. They demand drainage. Even in such conditions a compound fracture may occasionally be promptly converted into a simple one by the agglutination of structures contiguous to the fracture, though the skin opening may remain free for drainage.

Absolute cleanliness is the first requisite in an attempt to convert a compound into a simple fracture. A razor, soap and water are essentials, and must be well used in order to cleanse the skin. The purity of the water used in washing the wound is of first importance. The removal of extraneous matter from the wound may be accomplished by a wash of hot water, but where grease, cloth, and dirt of various kinds are adherent to raw surfaces, the fingers, forceps, etherial soap, turpentine, and sublimated washes may fail to accomplish perfect cleanliness, though the wound may be rendered aseptic and heal readily. A fairly perfect adjustment of the fragments is a requisite of early healing. Maintenance of the adjustment by a well-adapted splint which does not provoke engorgement and pain by undue pressure, is a most important item in the treatment. Many compound fractures where the local conditions would permit primary union of the wound, fail to progress favorably on account of the injudicious application of an apparatus which is good in itself but is imperfectly applied.

The external wound may be hermetically sealed by suture and collodion, if it is small and the soft parts are not extensively bruised. Where the skin wound is extensive, that portion of it which overlies the fractured bone should be closed by suture, if a point favorably situated for drainage can be found somewhat removed from immediate contact with the bone.

If the bone is protruding and has been contaminated by clothing, by a dirty skin, or by external objects, it must be thoroughly cleansed by careful picking and sponging, and then washed with an antiseptic solution, in order that aseptic conditions may be obtained. If the protruding fragment is not essential to solid union, the difficulty of cleansing its surface and the doubtful vitality of the long sharp points of bone, which are denuded of periosteum and bruised by violence, justify its removal by bone nippers or saw. In the more extensive injuries, where direct violence has crushed the soft tissues, comminuted the bone, and driven foreign matter into the wound, the cleansing of the parts and the removal of dead tissue will very often require an enlargement of the wound or an incision to give free access to the injured parts. Fascia and muscle if irretrievably damaged must be cut away with the scissors. Loose fragments of bone are to be removed, and a complete knowledge of the extent of the

* Trans. American Medical Association, Surgical Section, 1894.

injury to the bone and to contiguous parts, including joints, must be obtained. Blood clots should be washed out, and after thorough cleanliness has been obtained, efficient drainage must be provided. The original skin wound may be closed and drainage be secured by special incision, or through an opening made for the inspection and cleansing of the wound. Every effort is to be made to avoid suppuration, as it will destroy still more tissue. It should be remembered that it is difficult to maintain a perfect asepsis about a wound which is slow in healing, hence even where the skin opening can be closed, it is important to so arrange bone and soft tissues as to favor the agglutination of soft tissues about the line of fracture, in order that it may be shut off from the external wound at the earliest possible moment.

Fragments of bone or sharp ends of the fractured surface must not be permitted by malposition to exercise undue pressure upon the soft parts. Angling at site of fracture must be corrected, and if the tendency to shortening is marked and not easily controlled, as it is, not infrequently, where the ankle joint is involved in the fracture, the shortening of the limb by excision of the fractured end is proper and is a conservative measure. The adjustment of the compound and comminuted bone may not be perfect, but it must be practically so good that undue pressure on the soft parts will not induce ulceration, and must be such as to give a good outline and a useful extremity.

Extension and lateral support are the two chief agencies in maintaining apposition of fragments. Wiring of bone and the use of ivory pegs are occasionally necessary and can be used to advantage in isolated cases. They are, however, rarely necessary, and are an obstacle to rapid and solid union, except where they overcome the greater danger of persistent and obstinate displacement.

A solid union will often result without serious constitutional disturbance, even when the fracture remains an open one. The exposed bone will develop granulations, and if a part of it is necrosed, separation by granulation along the line of junction of the dead and living bone will occur, even while new bone is forming at other areas in the line of fracture.

Cleanliness, an easy and comfortable position for the fractured member, free drainage, and a good constitutional condition will generally insure solid union, though it may be long delayed. Union of bone in a compound fracture is much slower than in simple fractures, or than it is in the compound fractures which are promptly converted into simple ones.

Delayed union should be tolerantly dealt with; a persistent maintenance of the conditions which favor the nutrition of the injured leg will very generally be rewarded by a good recovery.

A thorough appreciation of the extent of the injury to the different structures of the extremity must be obtained in cases where the judgment wavers between an effort to save the limb and an amputation. Amputation should be immediate—that is, it should be promptly enforced as soon as the shock has passed, or postponed until the acute inflammation has subsided. A so-called secondary operation is safer than an immediate one.

The perfected technique of aseptic surgery enables us to save many extremities where suppuration with its attendant damages must have supervened and destroyed the limb before the details of antiseptic and aseptic methods were well understood. No less important is the selection of a splint which permits cleanliness, and at the same time insures rest and the undisturbed position of the fracture, which is so essential to the rapid repair of the soft parts and the union of the broken bone. The suspension splint of Dr. John T. Hodgen, with its extension and free motion, is a most important adjuvant in the treatment of componnd fractures of the leg and thigh.

Permanganate of Potash in Thrush. Ω

Drs. Troitski and Karntski (*Gazetta Degli Ospitali*) regard the permanganate of potash as the most efficacious remedy in the treatment of thrush in children. Besides application of an alkaline solution they also employ the permanganate locally in solution. A 2–4 per cent. solution of the bicarbonate of soda may be employed for alkaline irrigation, or in very grave cases a saturated solution of this substance. Besides this the physician should touch, two or three times a day, the affected spots with the following:

℞ Permanganate of potash.....25 | 0 (grs. iv.)
Distilled water.....30 | 0 (℥ j.)

Under the influence of this antiseptic the disease rapidly disappears.—

ICE-COLD APPLICATIONS IN ACUTE PNEUMONIA.*

THOMAS J. MAYS, A.M., M.D.,† PHILADELPHIA.

While cold applications in the treatment of pneumonia are by no means a new procedure, I am of the opinion that this has not yet received the consideration and extensive introduction which it merits, and in saying what I have to say to-night, I trust that I am loyal to that spirit which prompts one to conservatism in the commendation of any curative measure until it has stood the test of experience. When, however, one has observed the magic changes which follow in the pneumonic condition under the beneficent influence of cold locally applied, as has been done by others as well as by myself on numerous occasions, I feel that this method has passed the experimental stage of clinical medicine, and I therefore hope that you will pardon me for appearing obtrusive when I again direct your attention to this subject.

Cold has been employed in the treatment of pneumonia for various purposes and in various ways. Jürgensen believes that the chief danger in this disease arises from the high fever, and which finally leads to cardiac failure. He appeals to the experiments of Zenker and others to show that high fever is detrimental to the fibers of the heart muscle and to those of the voluntary muscles. He therefore recommends cold principally with a view of reducimg the pyrexia. It is a question, however, whether a high temperature of itself is more fatal in pneumonia than a low one; but this is a point which will be referred to later on. So far as I know, Niemeyer was the first to apply cold immediately to the chest for the purpose of reducing the activity of the local inflammatory process in the lungs.

It must be seen that these different views govern the practitioner in the mode of applying this remedy. If he believes in the constitutional nature of the disease, and especially if he thinks that the high fever endangers the integrity of the heart muscle, his principal aim is to reduce the fever at large, and to accomplish this he immerses his patient periodically in a cold bath, which is done by Jürgensen and others. If he holds that the local trouble in the lung is responsible for the high fever, and that this constitutes the vulnerable point in the disease, he will pay less attention to the general condition and make his cold applications directly over the inflamed lung.

I believe that much of the ill-success which has followed the use of cold in pneumonia is attributable to the fact that it was employed according to the first method. The pyrexia of pneumonia is not the same as that of typhoid fever, or at least it does not yield to cold in the same way as that of the latter does. The former is best subdued by cold being applied directly over the affected lung as well as to the head, and general baths or spongings do not seem to be essentially indicated, and if the latter are applied they do not keep the fever down for any long period. If the fever and a great deal of the constitutional disturbance of pneumonia depends on the inflammatory process in the lung, then an abatement of the pulmonary disorder will strike at the very root of the difficulty, and it is clear too that the measure which accomplishes this must be applied continuously and persistently, and not, like in typhoid fever, at stated intervals. Moreover, it is a hazardous procedure to subject a pneumonic patient to the bodily changes and cardiac strain which are incidental to the giving of a general bath. It must be remembered that the heart is always implicated in pneumonia, and is therefore a weak and easily assailed organ.

How then is the cold to be applied, and how long must it be continued? The affected area must be surrounded with ice contained in bags which are wrapped in towels. If the disease is confined to the front base on one side, one good-sized bag will suffice; but if the exudation extends to the side and back, then at least one more bag must be applied laterally and as far back as possible. If the affection is

*Read before the Philadelphia County Medical Society September 26, 1894.

†Professor of Diseases of the Chest in the Philadelphia Polyclinic, and Visiting Physician to Rush Hospital for Consumptives.

extensive, put on as many ice-bags as are necessary to cover the whole area. Watch the morbid process, for it is very apt to migrate from one spot in the chest to another, and if it does so, follow it up with the ice-bag.

The length of time for which cold is to be used must, in most cases, be decided by the amount of fever which is present. If this falls to or near the normal point, and shows a tendency to remain there, then the ice may be gradually removed. It is best, however, not to be in too much haste in withdrawing the cold, for frequently before this is off very long the temperature suddenly flies up again. If this takes place, and the temperature remains high after the ice is reapplied for some time, it is a possible indication that the inflammation has invaded a new field, and is not active in the old one. This has happened several times in my experience.

It must always be borne in mind, however, that the ice is not solely employed for the purpose of reducing the fever, but rather with the object of circumventing the exudative process and of hastening resolution in the affected part. There may be very little fever present in some cases of pneumonia, as in the aged, yet the destructive changes are going on in the lungs at a rapid rate. In senile and latent pneumonia the activity with which the ice is employed must be governed entirely by the impression which is made on the pulmonary disintegration. This must be the objective point and not the temperature.

This brings me to say something on the fever in pneumonia as a prognostic sign. Although a temperature of 105° F. is generally regarded more dangerous in the adult than one of 102°, I really believe that this is an error. When the fever is excessive, as when it rises to 107° or 108°, every one admits that this is almost necessarily fatal; but it must also be granted that a markedly low pneumonic temperature, as for example 95° or 96°, is equally fatal. The safety point, if such there be, lies somewhere between these extremes; and within a certain range I think we can look upon this fever as an indication of the degree of vital resistance which is present in the body. If it remains between 104° and 105°, the prognosis is good, provided other conditions are equal; but if it is either very high or very low, it is evidence of serious exhaustion and of vital inadequacy to cope with the destructive forces.

This opinion is partly confirmed by the high authority of Dr. Wilson Fox, when he says, on p. 352 ("Diseases of the Lungs and Pleura"), that "the extent of the pyrexia has a less unfavorable influence on the prognosis than might be expected." Out of a total of 353 cases he shows, on the same page, that the mortality from 107° to 110° was 100 per cent.; from 106° to 107°, 42.8 per cent.; from 105° to 106°, 18 per cent.; from 104° to 105°, 7.4 per cent.; from 103° to 104°, 17.6 per cent.; and under 103°, 36.9 per cent.

What, now, is the local action of cold on the pneumonic process? This, I believe, consists in its powerful influence on the pulmonary capillaries and in its ability to resolve the exudate and infiltrate. It is well known that the most apparent lesion in acute pneumonia is an enormous distention of the pulmonary capillaries, with partial or complete stasis of the blood in these vessels, exudation of fluid constituents of the blood, and proliferation and accumulation of epithelial cells, and diapedesis of white and red blood-cells in the alveoli and bronchioles. Now it is well known that cold has the power of contracting blood-vessels, and from this action it can be understood why it should be of benefit in pneumonia. But how it can dissolve an exudate or an infiltration is not so clear to me. That it accomplishes this I am firmly convinced. For example, there is a pneumonic area which is wholly devoid of vesicular sounds, and has a flat percussion note and bronchial breathing, indicating beyond doubt that the process has passed beyond the stage of engorgement and into that of exudation or of infiltration; yet the application of ice to this spot will in a remarkably short time develop a new group of physical signs, such as crepitation, reappearance of the vesicular murmur, diminution of flatness, etc. This has not only been observed by myself over and over again, but is also dwelt on by Dr. Lees, who had an extensive experience in the use of ice in this disease, when he says (*Lancet*, November 9, 1889, page 894): "In many cases I noticed a striking arrest in the development of the physical signs," and that the ice-bag "distinctly tends to repress the inflammatory process in the lung."

Is the ice treatment applicable in croup-

ous or in acute catarrhal pneumonia, or in both forms of the disease? In my earlier experience I inclined to believe that it was only adapted to the treatment of the croupous variety, but further familiarity with the measure taught me its use in the acute catarrhal form. I have also given it a trial in chronic broncho-pneumonia and in pulmonary phthisis, but with rather indifferent results, if not with positive harm in some cases. I must admit, however, that in several cases of this kind it seemed to do exceedingly well. It must be borne in mind, too, that the ice-bag is strongly recommended by the late Dr. Brehmer and by Dr. Detwiler and others in the treatment of chronic lung trouble, and with such excellent testimony in its favor it is very probable that many of us do not yet understand the specific indications for its use.

Besides being useful in croupous pneumonia and in acute catarrhal pneumonia, it also has excellent effects in the capillary bronchitis of infants and in the catarrhal pneumonia which follows measles, diphtheria and scarlet fever.

It is also desirable in this connection to say something regarding the heart in this disease. From the tenor of much that is said and written on pneumonia at the present time, one receives the impression that more is to be feared from cardiac than from pulmonary failure. That the heart's function is impaired no one will, I think, deny. Indeed, this could not be otherwise, for the heart and lungs have a common nerve supply, are bound closely together by the pulmonary blood-current, and whatever invalidates one must also affect the other; but I believe that the doctrine that pneumonia becomes fatal because the heart is unequal to the work of forcing the blood through the engorged lungs, and all that we are required to do is to stimulate and to goad this organ, unmindful of what is going on in the lungs, is as imaginary in its conception as it is fatal in its practice.

The pulmonary circulation is undoubtedly obstructed, and there is no question but that the heart chafes, frets, and becomes seriously embarrassed. Dr. Wilson Fox (op. cit., p. 285) says that "one of the most important consequences of pneumonia on the circulation is the occasional occurrence of thrombosis in the pulmonary vessels leading to the affected part. This event, caused in all probability by the retarded circulation in the lung, is no uncommon, and may, by extending to the larger branches of the pulmonary artery, be a source of immediate danger from sudden death, and may also, in great probability, retard the process of resolution and the subsequent convalescence." But is this any reason why we should whip up this organ in the hope that it may perform an impossible task, and stand by and do nothing to alleviate the blockade in front? Is this sound sense or physiological reasoning? No. We must discard this cart-before-the-horse theory and make strenuous efforts to remove the difficulty in the lung, and in this way liberate the heart from its entangled situation. To accomplish this very end there is no measure more efficacious than ice, and besides removing the engorgement and even the exudation in the affected lung, it also acts as a powerful stimulant to the heart's function. Indeed, it is chiefly for its serviceable influence on the heart that the ice-bag is recommended in chronic lung diseases by Dr. Brehmer and others.

In conclusion, I beg to say that the external application of cold in typhoid fever has reduced the death-rate from this disease to almost nothing, and I am sure it is not too much to presume that the same remedy, although differently applied, will do the same in the case of pneumonia. My opinion is based on what I have seen in my own practice and in that of others. In my collective report of fifty cases from various sources (see *Medical News,* June 24, 1893), there were two deaths. Since the publication of this list, I received abstracts of seventeen other cases treated by Dr. Jackson, of Brockville, Ontario, together with seven cases collected by myself, without a death, neither the histories of which, nor those of Dr. Jackson, had I time to write out since receiving the kind invitation from your Board of Directors to prepare a paper for this evening—making in all seventy-four cases of pneumonia treated with cold applications, and two deaths; or a death-rate of 2.70 per cent.

Now, the death-rate from pneumonia, when treated according to the current methods, is variously estimated from 20 to 30 per cent., hence the results from the cold-water treatment are at least ten times better than those which are obtained by other methods.*

MASSAGE *VERSUS* REMOVAL OF THE SOUND-CONDUCTING APPARATUS IN NON-SUPPURATIVE CASES OF DISEASE OF THE EAR.*

LOUIS J. LAUTENBACH, M.D.,† PHILADELPHIA.

It has of late years become more and more evident that the symptoms of defective hearing, tinnitus, and vertigo, when not due to a disease of the auditory nerve, are occasioned not by a pathological drumhead, but rather by some lesion in the sound-conducting apparatus. The ossicles, instead of being freely movable one upon the other, are more or less rigid from abnormal attachments between them, or the walls of the middle ear cavity, or both. In consequence of these attachments the true arch of the ossicles has been disturbed and the stapes is driven into the oval window, often ankylosed, causing pressure on the labyrinth. This pressure on the labyrinthine fluid occasions the periodical vertiginous symptoms as well as the tinnitus, the defective hearing being due to the rigidity of the conducting apparatus and the contraction of the ossicular arch. This conducting apparatus may be compared to the levers and hammers of the piano. When the key is touched, if the joints of the levers are freely movable the hammer strikes the vibrating string; but should there be any rigidity in the mechanism the key must be struck with more force to produce an equal effect.

The membrana tympani, to which formerly such supreme importance was given as the essential to hearing, is now known to be of little value in this respect, serving as the outer fixation point of the ossicular chain and preserving by its elasticity the normal ossicular arch, being to some extent a protector of the middle-ear cavity, preventing the ingress of foreign bodies and being only to a slight extent concerned in the function of hearing by concentrating the sound-waves to the handle of the malleus. It is to the proper movements of the ossicles that we are indebted in the main for the conveyance of sound. If these are abnormally limited in their motion, either by attachments or overweighting, or by a shallowing of the middle-ear cavity, due to the impaction of the stapes or retraction of the membrane, thus shortening the ossicular arch, sounds are not carried at their normal intensity.

It is to these cases of ossicular attachments, overweightings, and shortened ossicular arches that the methods of treatment, pneumo-massage, and ossicular removals are adapted. Ossicular exercise, which I usually term ossicular massage, has for its object the regular movement of each ossicle one upon the other, with the consequent changes brought about as to the nutrition of their joints, from the friction and the increased circulation. It aims to increase the length of the shortened ossicular arch and also to draw out into a normal position a retracted or adherent membrane, while at the same time it endeavors to loosen a jammed stirrup or one more or less adherent to the oval window. In addition to this, pneumo-massage slightly influences the round window and the internal-ear fluids within, and likewise exerts some effect on the upper end of the Eustachian tube, as well as the entire mucous lining of the middle-ear cavity. Its action is mild and regular, simulating the effects of a well-trained masseur. It stimulates the parts, puts the mucous membrane into healthier condition, hastens the absorption of all morbid deposits, and gives to the muscles and ligaments their normal activities, and at the same time amplitude to the joint movements. Its action being a drawing out of the drumhead, with a corresponding outward motion of the attached ossicles, is therefore directly opposite to that produced by air-concussions and loud sounds, which so often, especially when continuous, occasion ear diseases, the whole tendency of modern ear use, due to the multiplicity of shops, factories, etc., being to drive in the drumhead and jam the stirrup in the oval window.

This method is not one of destruction, but of construction; it removes nothing; it allows the parts to remain intact, while it gives to them normal exercise of the

* Read before the Philadelphia County Medical Society September 26, 1894.

† Surgeon to the Pennsylvania Eye and Ear Infirmary; Throat and Nose Physician to Odd Fellows' Home, etc.; late Chief of Eye Clinic, German Hospital.

muscles, ligaments, and articulating surfaces, and an increased and healthier circulation, with correspondingly increased and healthier secretions.

The practical deductions which I have reached, as the result of my use of ear massage, are:

1. The method is not difficult to apply, and can be used by any one who has a proper conception of the structure and functions of the ear, with a knowledge of the pathological conditions present.

2. There is no risk. It has never occasioned harm nor made the symptoms worse, nor does it in any way interfere with other treatment.

3. Should it fail in accomplishing the desired result, it does not prevent the use of further measures.

4. It has improved the hearing in over 90 per cent. of my cases.

5. In about 90 per cent. has the tinnitus been relieved.

6. It has perhaps in a little over the half removed the vertiginous symptoms.

Ossicular removals aim to relieve the same conditions by destroying the continuity of the conducting apparatus by taking out either one or more of the ossicles to the outer side of the ankylosis, usually removing at least one of the ossicles of the ankylosed joint. Of late years this has been modified by, in addition to removing one or more of the ossicles, mobilizing the remaining bone or bones.

As to the practical value of these operations, there is considerable difference of opinion among operators, but I believe the following statements will meet with little or no opposition from the impartial observer; they are formulated from the observations and results of many operators:

1. These operations are difficult. They require considerable skill and experience. Often the operator is not able to see what he is doing, but must feel his way very carefully. They should be reserved for the ear surgeon, as being the one most to be trusted with such delicate work.

2. The risks are considerable. Cases of permanent facial paralysis, persistent vomiting, and even death have occurred; whereas temporary palsy, acute inflammations of the middle ear, and caries are not uncommon results of the operation. Sometimes the very symptoms which called for the operation are exaggerated after its performance.

3. Should the operation prove a failure, it usually prevents the adoption of other measures, being thus truly a last resort.

4. It improves the hearing in perhaps a little over 25 per cent. of the cases.

5. It relieves the tinnitus in about 50 per cent. of the patients.

6. It has in about half the cases removed the vertiginous symptoms.

Having found, in a case unattended with suppuration, the ossicles to be rigid and not responding to the old treatment, we have either to pursue the massage method or that of ossicular removal; but it will be asked, How are we to decide between the two? There is no need to decide between them; the massage treatment should be instituted, and if unsuccessful, then are we to consider the question of operation. I do not believe any case should be operated upon until after the patient has been at least three months under treatment. I have heard operators say that they never operated until after they had thoroughly examined and for a long time treated the patient, and yet I remember one day in April of last year three patients presented themselves at my ear clinic who had been advised to have the operation performed, not one of whom had been under treatment for the ears, even as much as one visit, the opinion being given upon their first visit to an ear clinic.

During these three or more months the patient should be placed under the best hygienic influences, should be treated locally (nose, throat, and ears), as well as generally. Any part of the body needing it should receive proper attention. The ear treatment should include systematic pneumo-massage, and if deemed necessary careful phono-massage. If, after three or more months of such persistent treatment, there is no improvement of any kind, and if we are convinced, in a case of impaired hearing, that the auditory nerve retains its functional value, or that the tinnitus or vertigo, or both, are so great as to justify it, then only can we properly countenance an operation. I feel sure that the need of such an operation will rarely arise, even in a very large special practice. Personally I have performed but twenty-four such operations in five years, treating in that time over 4,000 ear patients.

The first of these I performed in March of 1889, removing the stapes as well as the

incus and malleus; the last in August, 1894, removing the incus only. In no other case have I advised the operation. I have held myself ready to do it in perhaps thirty or forty more, telling the patients that perhaps later it might be necessary, but the need for it has been dissipated by treatment.

There are distinct fields for the use of the massage and the removal treatments, the latter being advisable only where the former fails. I do not think that removal should ever be done without the previous continuous use of massage. To subject patients to operations, with the risk of making the conditions worse, and even that of death, when not absolutely necessary, I consider most reprehensible. After you have tried, and thoroughly tried, all the means at your disposal, including the proper and systematic use of massage, then only, if the symptoms should prove of sufficient gravity, will you be justified in subjecting the patient to the risks before mentioned. I have seen so many of the bad results of ossicular operations (in fact, more than the entire number of operations I have myself performed), and I so often meet with those who have been advised to have it done, and yet have not had their ears thoroughly treated, that I feel it to be necessary to condemn these operations unless they are done as a last resort to relieve either most distressing symptoms or to endeavor to restore hearing which cannot be otherwise improved. For the past few years there has been a great degree of recklessness in advising patients to have these operations performed. I remember the case of a patient with a watch-hearing distance of as much as eighteen inches (18:52) in the to-be operated ear, without vertigo, and but little tinnitus, being so advised. Now what were his chances of gain? Very little, as compared with his chances of loss. He almost surely would have been worse had he submitted to the operation. I will mention a typical case more fully. It proves interesting, from the fact that about six months' treatment has done for her more than any such operation could possibly have accomplished.

Mrs. E. H., aged forty-five years, in the winter of 1891 to 1892 had an attack of the catarrahal type of la grippe, during which time marked tinnitus of both ears developed, with defective hearing of the left ear. In May of 1892, on account of a hypertophic nasal catarrh, she put herself under the care of a throat specialist, who, to some extent, relieved her of the nasal trouble. The ear-symptoms increasing, she was sent to an ear specialist in October, 1892, who advised her, after examining her on two occasions, but not subjecting her to any treatment, that the disease of the middle ear demanded the removal of the ear-bones—that no other treatment was useful, whereas this operation was followed by good results in more than ninety out of one hundred cases; consulting her family doctor, he advised against the operation.

In February of this year she came to me, having in the mean time used no treatment except salt water for the nose and throat.

On examining the left ear, I found that she was troubled with extremely annoying tinnitus, with occasional vertigo, and that she could barely hear a fifty-two-ichn watch on contact; on the right side she had a hearing-distance for watch of twenty-two inches, with occasional tinnitus only.

The left ear, the one which she was advised to have operated upon, was the one to which I devoted my attention. After finding very marked retraction of the membrane, with little or no motion of the ossicles, and finding the auditory nerve in good condition, I subjected the ear to both pneumo- and phono-message, especially the former, twice a week, with the result that her hearing has markedly improved. She now hears the watch at thirty-eight inches, a greater distance than in the good ear, in which she hears it at thirty-four inches.

In the left ear there is occasional tinnitus, only upon taking a head-cold; the tinnitus in the good ear is now more noticeable than in the bad one. The left drum-head, which was formerly retracted and of a dull leaden hue, without any ocular evidence of blood circulation, is now normal in shape, somewhat of a pearly pink color, and fairly well nourished.

In this case the tinnitus has almost entirely disappeared, there is no vertigo, and her hearing is quite fair for one of her age, much better than I have ever seen as a result of an operation on the ossicles. The ear in which the operation was to be

done, indeed, is now better than the ear supposed to be good.

Is it not better to use a method which is painless and which is unattended by any risk, local or general, one which is almost always successful, at least in some degree, and which leaves the anatomical structures so that, if necessary, we can apply other methods, and which, if unsuccessful, at most delays future treatment for from three to six months only, than to subject the patient to an operation which is painful, uncertain in its effects, one which destroys structures that cannot be replaced, so that if unsuccessful, which it is in more than half the cases, the patient leaves all hope behind, and which sometimes intensifies the very symptoms for the amelioration of which the operation was performed? It seems to me that there can be but one answer. In non-suppurative cases of ear disease use massage and other necessary treatment first; in case of failure, then only, the operation.

ALTERATIONS OF THE URINARY STREAM.

Dr. Alexander Payer, of Zurich (*Wien. Med. Presse*), has made a study of the changes in the urinary stream.

Projective Force of the Stream.—A strikingly long stream is characteristic of a pathologically developed detrusor, due to hindrances to micturition in the urethral canal, such as follow moderate strictures, a narrow external orifice, or from spasm of the detrusor. Weakening of projective force of the current is, at a certain age, pathognomic of prostatic hypertrophy, and is seen in weakening of the detrusor from chronic inflammation of the mucous membrane and muscular tissue, from neglected gonorrhœa, in atony from fatty degeneration of the muscular tissue, as in the course of acute infectious diseases, like typhoid fever or dysentery, and from voluntary retention of the urine where micturition is painful, as in stone in the bladder and fissures of the neck of the bladder. A decrease of force is observed in neurasthenics and in spinal diseases and tabes.

Decreased Caliber of the Stream.—Hypertrophy of the prostate, or stricture, will diminish the caliber. In prostatics the current falls vertically down, and in stricture as well, but in the former the force is not increased by pressing, while in the latter it is. Spasmodic contractions of the urethra from general diseases may also cause a diminution of the caliber.

Altered Form of the Stream.—A deviation from the round form is observed as the earliest sign of stricture. In decreased force of expulsion the form is changed. Change of form is not a certain sign of stricture.

Continuity of the Stream.—Sudden stopping of the stream is supposed to be pathognomic of stone, but it is rarely observed except in children. In adults, the stone must be very small and light. It is, relatively, frequently remarked in spasm of the sphincters in neurasthenics.

Starting the Stream, etc.—A drop-by-drop passage of the urine is characteristic of great stricture and great pressure. In some cases there follows a round and strong stream when it started drop by drop; spasm of sphincter.

Dripping of Urine.—Dripping of urine after passage of the stream is a frequent occurrence, and is of varying importance, according as it appears after voluntary urination—a short time after—or in the intervals. It is due to a relaxation of the muscular tissue of the urethra, and the urethra lying in a half-opened condition does not press the urine out over the bulbous portion, so that it accumulates and is suddenly ejected after urination, or it drips away slowly during walking. Narrow strictures also cause it, where the portion posterior to the stricture fills like a sack, and unless emptied by milking movements by the patient, it drains away afterward. Abnormal narrowness of the orifice or very great phimosis are other causes. Involuntary urination may occur at any time, while dripping only follows urination.—*Mass. Med. Jour.*

EDITORIAL.

THE ETHICS THE LAW TEACHES.

The "code of ethics" has been rather elaborately treated in our medical journals and societies. Many of those discussing the ethical questions inseparable from the honorable practice of the medical profession, do not stay down close to the ground where men live and their work is done, but take flight into the ethereal in seeming blind search for some new beatitude. It is not with the "irregularities," the palpable immoralities, nor those digressions from the lines of professional duty as marked out by the schools, that it is our present purpose to deal. It is with the too free dealing with names and characters, with the slurs, epithets and, what is worse and more damaging, the calumnies uttered against men who have their professional lives to live.

Imputations are something more than the allegation of mistakes or the common imperfections of humanity. Harsh opinions are often ventured upon circumstances and conditions stated by others, and without personal knowledge of the specific facts. An uncharitable opinion may have its foundation upon premises easily fabricated, but the fact of being fabricated does not deprive them of their vicious and damaging elements, nor does it relieve the calumniator of responsibility.

The report of a single act of delinquency, if credit be given it, is at once fatal to the most exalted reputation. Reflections upon a man's conduct or principles necessarily tend immediately to debase him, to degrade him from the position he holds in the favor and esteem of others, and to exclude him from enjoying that degree of success to which his merits entitle him. Every man has the right to the enjoyment of the character and reputation which are the creations of his own exertions and self-denials.

The physician's chief capital is the confidence of his patrons and that of the fellows of his profession. The one who by libelous or slanderous speech impairs or deprives him of this confidence is as much a wrong-doer as if he had deprived him of some specific article of property. The nature of these injuries excludes remedy by restitution. That cannot reach and correct the mischief done. Recanta-

tion is unsatisfactory; it bears the stamp of suspicion and is often forced. Apology always comes too late. Such remedies do not reach down and eradicate the motive and intent, nor go out and undo the evil done. It is impossible to determine how far spoken words of defamation will extend by innuendo. Character and reputation are peculiarly susceptible of injury. Confidence in an individual is destroyed by slight causes. Hence the importance and general necessity of protecting reputation, where the "code of ethics" or the preventive restraints exercised within the profession fail, by the restraints of law through such provisions as meet the exigencies of each and all cases as they arise. The law from the soundest and most obvious principles of justice interferes to protect the man, whatever his occupation or profession, from unjust and malevolent aspersions which deprive him of the profits and advantages which, as a member of the community, he is entitled to enjoy.

Where imputations affect a man in his profession or means of livelihood, the law gives a substantive right of action (Starkey), though the party slandered may be unable to prove any specific loss or damage. This for the reason that a man might be effectually ruined in his business by the slander before his proof of specific damage could be completed. Hence the general rule that words are actionable, without proof of special damage, which directly tend to the prejudice of any one in his profession, trade or business. Said of a surgeon, "I wonder you had him to attend you. Several have died that he had attended, and there have been inquests held on them"—these words were held actionable. So also the words, "He is a bad character. None of the medical men here will meet him," have been held actionable as imputing the want of a necessary qualification for a surgeon in the ordinary discharge of his professional duties.

Generally, it may be said that any words spoken of a professional man that imply unfitness, incapacity or gross ignorance or unskillfulness in his profession, are actionable. This applies in all cases where special damage can be inferred as the natural result or probable consequence of such words. It is actionable to charge a physician with malpractice; case in point: "He killed my children; he gave them teaspoonful doses of calomel and it killed them." This, although a specific charge, was held nevertheless to be a general imputation of malpractice, which amounts to a charge of general ignorance or want of skill. So the mere fact that words relate to a specific case does not strip them of the character of a general imputation, if their effect is to make a general charge of ignorance or want of skill. The false and slanderous may be spoken of a physician's practice in a particular case, ascribing to him only such a want of information and good management as is compatible with great general knowledge and skill in his profession, and when such a case arises, unless some special damage exists, his character will be considered as unhurt and no damages will be presumed. But, on the other hand, it is indisputably clear that a calumnious report concerning a physician in a particular case may imply gross ignorance and unskillfulness, and do him irreparable damage. A physician may mistake the symptoms of a patient, or may misjudge as to the nature of his disease, and even as to the powers of medicine, and yet his error may be of that pardonable kind that will do him no essential prejudice, because it is rather a proof of human imperfection than of culpable ignorance or unskillfulness. On the contrary, a single act of omission of his may evince gross ignorance and such deficiency of skill as will not fail to injure his reputation and deprive him of general confidence.

It is needless to quote further words made actionable by the law. The law,

applying itself to the urgency of these cases, to the protection of character and reputation, proceeds by assessing pecuniary damages for the mischief done. Probably no other method would be so effective in promoting discreet speech as risk of draft upon bank account.

There can be nothing objectionable, legally or ethically, to just and fair criticism of professional qualifications. Such is needful for the correction of errors and to make possible advances in knowledge, but persons in exercising this privilege must confine themselves within the limits of the truth, and are not licensed to traduce or caluminate character by false or malicious statements, recklessly made for the furtherance of private malice or personal ill-will. By harsh, unjust and uncharitable criticisms, by the lash of the tongues of men who never pause to consider the gravamen of their accusations, many a worthy man has been driven to the wall. If every man, professional or other, would carefully study his own experiences he would reverse his judgment as to many of his fellows.

There are men in the profession who would seem to rather pride themselves in their roughness, in their ignorance of those little amenities, the small courtesies and charities of act and speech so easy of practice and so grateful to the recipient. The important consideration in which they alone hold themselves and their professional selfishness prompt them to decry and apply ungenerous and damaging epithets to the fellows of their profession. They would make up for the want of larger ability by noise and bustle. Such men forfeit largely that valuable esteem of the profession and that regard of the communities with which they are in touch, and upon which their influence and usefulness largely depend.

As there is a common sense in men which detects sham, so there is a better sense which detects and despises the ungenerous. All good men and women love to come within the sphere and attractions of those who appreciate and practice what has been called "the small, sweet courtesies of life." It is impossible to measure the extent to which these courtesies take hold of and influence men. They are the talismanic influences which make names to be honored, and which open and widen fields of work and usefulness. The constant exercise of good offices, of professional aid and friendship, will help along a difficult way many a hard-pressed, struggling man.

THE TREATMENT OF STYES.

The *Gazette Médicale de Paris* publishes an article on this subject by M. Ripault, who recommends the repeated applications of antiseptic compresses. After the pus has formed an incision is made and slight digital pressure is employed to aid in the expulsion of the core; hot compresses accomplish the rest. In order to prevent a return of the symptoms, an antiseptic ointment consisting of seventy-five grains of vaseline and three-quarters of a grain of yellow mercury oxide should be applied to the eyelids every night, and both morning and evening the eye should be bathed with a warm solution of borid acid in water or of corrosive sublimate, without alcohol, in the proportion of a grain and a half to fifteen ounces and a half of water.

The preventive treatment is based on the etiological diagnosis. The conjunctiva, the lachrymal ducts, and derangements of refraction are treated; the patient is instructed to take special precautions (using green protectors, avoiding scratching of the eyes, etc.) when his work exposes him to any irritating action, above all if he is subject to inflammation of the eyelids. The general condition should never be neglected. If there is a furucular diathesis, alkaline preparations should be employed such, as sodium arsenate or bicarbonate, and tar water; if the patient is of a lymphatic temperament, tonics and iodized preparations should be employed, and finally, at times, an antidiabetic diet may be useful. The treatment should then be not only curative but above all preventive, and should be local and general.—*N. Y. Med. Journal.*

ABSTRACTS.

VIQUERAT'S TREATMENT OF TUBERCULOSIS.

ARTHUR GAMGEE, M.D. Edin., F.R.S.

The sensational paragraphs which have appeared in various continental journals, and which have been copied into the English papers, announcing the startling discovery of a new and certain method of treating phthisis and other tuberculous affections induced me to telegraph on Tuesday, September 19th, to Dr. Viquerat, of Moudon, asking him whether he would be at home on the following day, as I wished to see him in reference to his treatment of tuberculosis. Receiving an affirmative reply, I left Lausanne by the 5.30 A.M. train and shortly after 7 A.M. reached Moudon, a quaint medieval little town, once the capital of the Canton de Vaud. I was received by Dr. Viquerat with the greatest courtesy, and in my interview with him, which lasted until midday, he manifested the greatest readiness to acquaint me with his method and frankly replied to every question which I put to him.

In the criticisms which I shall feel called upon to make, and the warning which I shall feel compelled to address, I must neither be understood to impugn Dr. Viquerat's good faith and veracity, nor to cast a slur upon his scientific capacity and his professional devotion. It will, however, be my duty to draw attention to the weak links in the chain of evidence which Dr. Viquerat adduces, and to show, as I think, conclusively, that his method of treatment is yet in the strictly experimental, or rather tentative, stage, and that the evidence in its support is insufficient to justify the confident anticipations which have been indulged in. Instead of building castles in the air only destined to be dissipated, let the friends of phthisical patients in England await the calm judgment of those able to form a sound opinion when the necessary experimental and clinical evidence shall have been laid before them and the means afforded of adequately controlling Dr. Viquerat's assertions. The experience of error into which so great an observer as Koch fell, and the fact (which I am bound to refer to) that Dr. Viquerat's enthusiastic nature has led him, on one occasion at least, to announce a therapuetical discovery which has disappointed all expectations, not only justify but compel caution. Dr. Viquerat may rest assured that neither praise nor gratitude nor honors will be grudged him if he prove successful in his struggle with that disease which surpasses all others in the victims which it claims; on the other hand, in the interests of humanity, the leaders of scientific medicine have a right to claim that they shall be allowed to examine the minutest details of alleged medical discoveries before these are submitted to the popular suffrage. The statements in this article which relate to the details of Dr. Viquerat's method of treatment and to his opinions are derived in part from a pamphlet lately published by him,* in part from a report† dated September 3, 1894, signed with the initials "G. P." and of which the writer is a young medical man until recently a student in the University of Geneva, but mainly from information directly communicated to me by Dr. Viquerat in my interview of September 20th.

Dr. Viquerat's method for the treatment of tuberculous diseases is based upon and suggested by principles and general methods which we owe in part to the great Pasteur and in part to two distinguished pupils of Koch, Behring and Kitasato. Pasteur had shown that animals could be rendered immune from the attacks of certain virulent infective diseases, such as chicken-cholera and anthrax, by inoculating them with successively increasing doses of attenuated cultures of the bacteria which occasion them. It was afterward found that protective immunity could likewise be secured by injecting cultures

* Das Heilverfahren der Tuberculose gegrundet auf bacteriologisch-experimentelle Studien. Von Dr. Viquerat in Moudon. Erste Auflage. Mouden Buchdruckerei. J. Kretz-Bettemann. 1894.

† Rapport sur les Resultats obtenous par M. le Dr. A. Viquerat dans son Traitement de la Tuberculose (Geneve, le, Sept. 3, 1894). Imp. Romet, Boulevard de Plainpalais, 26.

sterilized by heat or cultures which had been freed from all bacteria by filtration through unglazed earthenware. Such sterilized or filtered cultures owe their immunizing properties to soluble chemical substances which are produced by the pathogenic bacteria, and which, when introduced in sufficiently large quantities into the animal organism, induce all the phenomena of the special bacterial disease. This immunity against tetanus or against diphtheria can be induced by repeated subcutaneous injections of gradually increasing quantities of the soluble toxic substances which are formed by the tetanus and diphtheria bacilli respectively. It is, however, to Behring and Kitasato that we owe the conception and the actual method for treatment of bacterial diseases by means of the serum of immune animals, and it is they who may be said to have introduced "serum therapeutics." They showed in 1890 that when the blood serum of rabbits which had been rendered immune from tetanus was repeatedly injected subcutaneously into mice these creatures, which are peculiarly susceptible to the tetanus poison, were in their turn rendered immune so as to be ultimately unaffected by the injection of the most virulent cultures of the tetanus bacillus or the strongest solution of its poisonous products. They found, moreover, that the serum of an immunized animal when mixed, outside the body, with a virulent culture or a toxic solution of its soluble products destroyed their power of inducing the phenomena of tetanus. Further, they discovered that the serum of animals rendered immune from tetanus when repeatedly introduced into the body of others already suffering from the disease caused the symptoms to abate and often led to recovery. These beautiful and wonderful discoveries led, in the first instance, to a rational method of treating tetanus as affecting man which, in the hands of Tizzoni, Javel, and others, has enabled them to save many lives which would otherwise have certainly been sacrificed. The same method applied by Behring to diphtheria has led to the treatment of this disease by the serum of horses rendered immune from diphtheria—the treatment which, as carried out by Dr. Roux, the distinguished Chef de Service of the Pasteur Institute in Paris, has reduced the mortality from 63 per cent. of all treated (the proportion of deaths in the cases occurring in a hospital when the old treatment was at the same time being carried out) to 26 per cent., and, as carried out in Berlin, has reduced the mortality from 41 to 15 per cent. of all cases treated (Aronson). If one considers that a large number of the 300 cases treated in Paris and the 274 cases treated in Berlin were in the last stages of the disease, and that in many the gravest complications existed, it cannot be doubted that when the treatment of diphtheria can be undertaken in its early stages the results will be still more remarkable, and that this dreaded disease will, through the beneficent researches of science, have been deprived in great measure of its power of evil.

Inasmuch as pulmonary phthisis and other tuberculous affections are the result of the activity of a pathogenic microorganism, the tubercle bacillis of Koch, it occurred to Dr. Viquerat to employ in this treatment the serum of animals immune from tubercle, and in the first place to endeavor to find some animal easily available to man which possesses a natural immunity for tubercle. It has been shown how *artificial immunity* from the inroads of pathogenic bacteria may be secured, and a few words must now be devoted to *natural immunity*. There exists a natural immunity, relative or absolute, which explains why certain individuals readily fall a prey to specific bacterial diseases, such as the infective and contagious diseases, while others escape scatheless who are placed under precisely the same conditions. There are instances of natural immunity possessed by certain of the lower animals which are very remarkable. Thus the common rat possesses *almost* complete natural immunity from anthrax, while the white rat is readily affected by it. In his inquiries Dr. Viquerat discovered that the only domestic animals which under the normal conditions of their existence have never been observed to become tuberculous are the ass and the mule. Even the horse, as the writer learns from a letter received from Dr. Guillebeau, the eminent Professor of Pathology in the Veterinary School of Berne, is so rarely the subject of tuberculous affections as to have been long held to possess a natural immunity from such diseases; its absolute immunity has in recent times been disproved.

In the articles which have appeared on the subject of the Viquerat treatment the

statement is made that it consists in the injection of the serum of asses' blood into the body of the person or animal affected, and in the pamphlet published by Dr. Viquerat, as well as in the report already referred to, allusion is only made to asses' serum without any mention of the animal yielding the serum having been subject to inoculation with tubercle. Dr. Viquerat, however, brought before the writer facts which prove that the immunity enjoyed by the ass is not an absolute one, and informed him that, in order to strengthen the natural immunity, he subjects the ass or mule which is to yield the immunizing serum to inoculation with cultures of the tubercle bacillus. The ass and the mule, according to Dr. Viquerat, though never becoming subject to tubercle under ordinary conditions and offering a far greater resistance than the horse, do not enjoy an absolute immunity under certain experimental conditions, though he asserts that in the case of these animals the tuberculous affection which is artificially induced *invariably terminates in recovery*. The natural immunity of the animal, he asserts, is reinforced by the temporary disease, so that its blood serum introduced into the body of other animals possesses the power of arresting the progress of tuberculous affections and (if these are uncomplicated) of curing them. The actual process employed by Dr. Viquerat in order to prepare the ass or mule which is to yield the serum for the treatment of tuberculous affections is as follows: 30 c.c. of an active bouillon culture of the tubercle bacillus are injected subcutaneously, and, immediately before or afterward, 15 c.c. of the same culture are injected into the blood-stream through one of the jugular veins. He asserts that subsequently the ass or mule exhibits no rise in temperature or other symptoms of disease, and that the only objective phenomenon is a remarkably voracious appetite. As the animal, according to Dr. Viquerat, invariably survives, no evidence of any tuberculous infection following the inoculation would be available had he not killed a series of donkeys at varying periods subsequent to the operation. As a result of these observations he asserts that if an ass or mule, treated as above described, be killed between the fifteenth and thirtieth day after inoculation, the lungs are found to be pervaded by miliary tubercles which are never surrounded by hyperæmic lung tissue. If the animal be killed between the thirtieth and fortieth day, Dr. Viquerat asserts that the tubercles are found to be disappearing, leaving no trace behind them, while after the fortieth day the lungs are always found to have returned to a condition of perfect health. It is from the forty-fifth day, when spontaneous cure has already been more than completed, that the animal is used to supply the curative serum. With this object it is bled, and the blood is allowed to stand over ice so as to allow it to clot and to permit of the separation of serum. To this serum from 0.5 to 0.75 per cent. of carbolic acid is added, and it is then stored in stoppered bottles until required for use. Without wishing to be hypercritical, I must point out that the above statements are of so remarkable and withal of so improbable a character that they cannot be accepted until the most complete and detailed record of each experiment is published, and until the results are confirmed by independent observers. The number of observations would have to be very large in order to establish the fact that the ass or mule is after inoculation into the blood invariably affected by an acute miliary tuberculosis of the lungs—*a miliary tuberculosis always terminating in recovery*. It may very reasonably be objected that, unless the chances of error were minimized by such a number of experiments as the costliness of the animal experimented upon almost precluded, the probability is that the asses which when killed exhibited pulmonary tuberculosis would in the natural course have succumbed, while those which when killed exhibited no tubercle had probably remained uninfected.

A further criticism which will suggest itself to all who are conversant with experimental bacteriology is that, while Dr. Viquerat has followed up to a certain point the method of Pasteur, of Behring, of Kitasato, and others of inducing immunity against a bacterial disease by inoculation of the bacteria which induce it, his method is altogether exceptional, as he satisfies himself with a single inoculation and furnishes no proof that he has thereby induced *absolute artificial immunity*. But "enough of these pedantic objections" may be the remark of the enthusiast, only too anxious that Dr.

Viquerat's predictions should be immediately accepted. "What are the facts on the strength of which Dr. Viquerat relies?" The first and, as it appears to me, the most promising of all the statements which Dr. Viquerat communicated to me was the following: that when the immunized serum of the ass or mule is injected every second day into guinea-pigs which have been fifteen days previously rendered tuberculous by the inoculation of active tubercle cultures, the tuberculous glands which had become enlarged and perceptible rapidly become smaller and disappear, while the animal, instead of dying fourteen or fifteen weeks after the inoculation, regains perfect health. If the observations made by Dr. Viquerat on this point be accurate, it appears to me that they offer the surest promise that *sooner or later* tuberculous diseases will yield to the treatment by the serum of animals rendered *perfectly immune* in respect of tubercle. But it is on the results which he has obtained in the treatment of tuberculous diseases affecting man that Dr. Viquerat in great part relies. Since February he has treated twenty-five cases, among which are many diagnosed as cases of pulmonary phthisis in its earlier and later stages, as well as others representing various forms of surgical disease *alleged to be* of a tuberculous nature, *no proof whatever being given of the fact.* His usual plan is to inject 12 c.c. of the prepared serum every third day. I saw two patients thus injected, and I can vouch for the fact that in neither of these had the numerous injections to which they had previously been subjected led to any local accident—such, for instance, as suppuration.

All the information which is furnished in regard to the twenty-five cases of alleged tuberculous affections treated up to the present time by Dr. Viquerat is contained in the so-called "report," to which allusion has already been made. This "report"* furnishes the most unsatisfactory and disappointing evidence which can be adduced in support of Dr. Viquerat's statements, and the amusing tone of authority assumed by its author is no less remarkable than the looseness of nearly every statement which it contains. Before criticising the list of cases given in this so-called report, it must be stated that at the foot of the document is printed the following announcement: "Sur la vue de ce rapport médical un Institut vient d'être créé à la Côte-Drize à Genéve, dans lequel M. le Dr. Viquerat continue ses travaux de recherche et où une clinique s'ouvrira le Nov. 1er, 1894. Les tuberculeux seront traités à *l'Institut Viquerat* dans l'ordre de leur inscription." Seeing the importance which, according to the paragraph just quoted, appears to have been ascribed to this so-called report, it would have seemed reasonable not to conceal the identity of its author, and to have furnished proofs, which are doubtless forthcoming, that he has now ceased to be *in statu pupillari*, and that his report may therefore be properly termed a medical report. But to return to the twenty-five cases of supposed tuberculous affections referred to in the report. I must point out that no conclusions whatever can be drawn from the results of the treatment of the surgical cases which are diagnosed as turberculous in character, as no grounds are given which permit of the accuracy of the diagnosis being tested. Hospital surgeons will share the skepticism of the writer in reference to cases reported as follows:

"Case 10.—R., Moudon, multiple cold abscesses, osseous tuberculosis, fistulæ. Improved; still under treatment

"Case 11.—L., Ermanche, tuberculosis of the radius, fistula closed. Pains ceased, improved; still under treatment.

Case 12.—C., Lucens, tuberculosis of the ulna, cold abscess of the neck. Cured."

Turning now to the cases diagnosed as pulmonary phthisis, it is found that they number 15 out of the total 25. Of the phthisical cases 8 are stated to have been in the first and second stages of the disease and 7 in the third stage—*i.e.*, cavities existed in the lungs; in 2 of these 7 cases laryngeal tuberculosis existed. Of the cases in the first and second stages the majority are stated to have recovered, but inasmuch as in these again no details whatever are given, one is compelled to be skeptical. The value to be attached to a diagnosis of phthisis in the first and even the second stage must depend entirely on knowledge of the skill and habitual accuracy of the physician who has made the diagnosis; great, however, must be the faith of the physician who would ac-

* *The Lancet*, September 29, 1894.

cept such notes of a case as the following:

"CASE 22.—M. G——, Penay, pulmonary tuberculosis, first and beginning of second stage. Cured.

"CASE 23.—P., Chesal, pulmonary tuberculosis, second stage; improved; still under treatment."

Passing now to the seven cases of phthisis in the third stage—that is to say, in which the disease had progressed to the formation of cavities—one is said to have recovered. The following are the notes of this case:

"CASE 2.—M. E. C——, Moulin de Penay; pulmonary tuberculosis, second and third stage; acute form (*forme galopante*). Cured."

Is one to suppose that the cavity or cavities have disappeared in the few months which at most have elapsed since this case was treated, or that by "cured" are understood cessation of morbid symptoms and apparent return to health? Unfortunately, the physician knows that even under such circumstances one dare not speak, after only a few months of respite, of a case of advanced phthisis being *cured*. Excluding this one case, of the remaining six cases of phthisis in the third stage one (No. 9) ceased the treatment and died; one (No. 24) became affected with pulmonary gangrene and stopped the treatment; one (No. 25) has not improved, but is still under treatment; and three are said to have improved somewhat, but to be still under treatment.

The above short analysis of the cases which have as yet been treated by Dr. Viquerat's method justifies the opinion, which I expressed at the commencement of this article, that this method of treatment is yet in a strictly experimental or rather tentative stage, and that the evidence in its support is insufficient to justify the confident anticipations which have been indulged regarding it.

Notwithstanding the criticisms which I have felt compelled to make, I would, in conclusion, state that it appears to me that Dr. Viquerat is engaged in the study of facts which promise to lead to results of the greatest practical value, but only on condition that he does not deceive himself and others by supposing that the discovery of the method of curing tuberculous affections is already an accomplished fact.—*Lancet.*

DIPHTHERIA TREATED BY ANTITOXIN.

Hunter Urquhart Walker, L.R.C.P. and S. Edin., late Medical Officer of Health, Worksop, Notts, says (*The Lancet*):

"I was so struck with the results produced, or apparently produced, by this drug that I determined to investigate the matter, and when I had a chance put antitoxin to the test. So I procured a small quantity of Behring's solutions. It is impossible, I know by sad experience, for the hard-worked general practitioner to be thoroughly versed in the great army of new drugs that we have in the market, and I may therefore be pardoned if I state here for the benefit of my readers one or two facts with regard to the drug in question. Antitoxin, I think, deserves special consideration from us, and I shall have attained my object if others will state their experience of the drug and say whether it does or does not bear out what has been said of the new specific.

"With regard to Behring's solution, it has been proved that if a mixture of 0.001 c.c. with the same amount of poison is subcutaneously administered to guinea-pigs, not only are no symptoms of disease caused, but also no local symptoms are observable, especially no infiltration at the place of injection. The antitoxin solution contains 2 to 2.5 per cent. egg albumen and a further admixture of 0.4 per cent. trikresol for preservation purposes. For the immunization of adults and elder children 1 c.c. of the solution is injected subcutaneously by means of a Pravaz syringe which has been previously sterilized by alcohol and three per cent. carbolic acid or one per cent. trikresol solution. For young children up to two years the dose should be 0.55 c.c. The above quantity of antitoxin thus administered to persons threatened by diphtheria is at least ten times as much as is required to render them immune. The immunity from diphtheria is therefore much more lasting.

"I was called in to see the patient, eight years of age, on July 27th. I was told she had been ill for a day or two. She had passed a very restless night. On the 28th the child seemed more restless, the color in the face was rather darker in hue, the pulse quicker and the breathing more difficult. The throat presented much the same appearance as on the previous day. On the 29th the child was distinctly worse, especially the breathing. The fauces on the right and left sides were covered with membrane. In the evening the respiration was very quick. On the 30th the membrane was well formed, even extending well over the soft palate and hanging down into the mouth. Up to this time the child had been treated with iron and chlorate of potash internally and the constant use of the lime-water spray. (One patient under my care just previously—a very bad one—did so remarkably well with the lime-water spray that I naturally did not wish to discard this method of treatment in favor of another of which I had little or no experience.) However, it was evident that something more would require to be done if the patient was to improve, for I noticed that in spite of the treatment another patch of membrane had formed in front of the curtain which hung down from the soft palate. I resorted to antitoxin. Eleven minims of antitoxin were then injected into the forearm with strict antiseptic precautions. The temperature at the time of injection was 103° F., and the pulse 140. In four hours after the injection the child was much improved. There was no fever and the pulse was quite quiet. She had a good night and had to be roused by the nurse to receive her nourishment, which throughout consisted of beef tea, chicken soup, brandy and milk and wine whey. On the 31st I noticed that the same improvement continued, although the membrane was still present. However, it was apparently loosening at the right side. My patient informed me that her temperature was 98.4° F., and I found she was nearly correct, as it was normal. During the day much of the membrane came away. The last patch to form had disappeared. All that was to be seen was on the uvula and on the left side. On August 1st all signs of membrane had disappeared, the temperature was normal and the pulse good. The patient begged to be allowed to have her picture-books in bed. The throat caused her no pain. From that date uninterrupted recovery took place.

"I would especially notice in this case that within a few hours the temperature was reduced four degrees and afterward remained normal. The constitutional disturbance was at once checked, although the membrane still remained on the uvula and left side of the throat. The new patch on the soft palate at once disappeared, and the appearance generally became more normal. The injection in this case, as in other cases where it has been used, was entirely innocuous, being followed by neither local nor general disturbance"

The following reports of cases in which this mode of treatment has been employed are from the *British Medical Journal:*

Mr. J. Townsend Barker, L.R.C.P. Lond., M.R.C.S.Eng., L.S.A., D.P.H. Camb., medical officer for Streatham, reports two cases:

Case I.—A. T., aged 2, a female; taken ill September 19, 1894, with sickness, feverishness and dullness. First seen in the evening, when a patch of membrane was discovered on the right tonsil the size of a threepenny piece. Treatment consisted of a mixture of perchloride of iron and glycerine given every two hours and the painting of the throat with sulphurous acid and glycerine.

September 20th. Temperature: morning, 102.6° F. Pulse, 144. Child dull and heavy. Both tonsils and soft palate covered with membrane and several patches on pharynx. In the evening the membrane was extending and paraffin was substituted for the sulphurous acid paint. The urine contained no albumen. Temperature: evening, 100°. Pulse, 144.

September 21st. The throat appearances as before, but membrane is thinner. A croupy cough has supervened and some laryngeal stridor. Temperature: morning, 102.2°. Pulse, 120. Urine: no albumen. In the evening the temperature had fallen to 98.4°; pulse, 132; the laryngeal symptoms continued though the child had been tent-bedded and steamed all day.

September 22d. The throat somewhat cleaner and less membrane on the pharynx; tonsils still covered; laryngeal stridor and cough continued, though ameliorated. Temperature: morning, 98.4°; child still dull and apathetic; pulse, 132. By the

kindness of Mr. Zimmerman I was furnished with mxx of Aronson's antitoxin, and in the afternoon I saw the child again in consultation with Dr. Wilberforce Smith and injected mxx into the outer side of the thigh. The previous treatment was continued. The child got brighter shortly after the injection. Temperature: evening, 98°. Pulse, 132.

September 23d. Temperature: morning, 97.4°; evening, 98°. Pulse: morning, 130; evening, 130. Urine: no albumen. Throat cleaning; laryngeal symptoms gone; child feeding well and much brighter.

September 24th. Tonsils and pharynx clean. No membrane visible; no laryngeal symptoms. No albumen. Temperature subnormal.

September 25th. A trace of albumen in urine, which disappeared the following day.

Henceforward the child rapidly regained strength, and no further complications have so far ensued.

Case II.—M. T., aged 27, mother of the above. Taken ill on September 22d. Felt chilly and prostrate all day. At night pains in back and limbs came on, with severe frontal headache and slight sore throat. A small patch of membrane was visible on the lower part of the right tonsil. Urine: no albumen. Temperature: evening, 102°. Pulse, 156. Treatment a mixture of perchloride of iron and glycerine every two hours, and paraffin as a throat paint every four hours.

September 23d. Temperature: morning, 100.8°; evening, 100.8°. Pulse: morning, 144; evening, 130. Thick membrane covered both tonsils. Urine: no albumen. Patient took plenty of nourishment, chiefly Benger's food and beaf-tea, and did not object to the paraffin. The throat was ordered to be sprayed with a solution of lactic acid ʒiij in ℥viij of lime-water alternately with the paraffin painting.

September 24th. Temperature: morning, 99°; evening, 100°. Pulse: morning, 124; evening, 110. General and local conditions same as yesterday.

September 25th. Temperature: morning, 97.6°; evening, 99.4°. Pulse: morning, 112; evening, 96. Urine contained a trace of albumen. In the evening the tonsils were cleaner than on the previous day, but coincident with a slight rise in temperature there was an increased feeling of illness and a slight formation of membrane on the anterior pillars of the fauces on each side. I injected mxx of Aronson's antitoxin (all we could obtain). The patient voluntarily described the effect of the injection as that of a powerful stimulant. The feeling of depression from which she suffered passed away in about half an hour, and never returned.

September 26th. Temperature: morning, 98.4°; evening, 98°. Pulse: morning, 112; evening, 96. Urine contained a trace of albumen, which has persisted till the present (October 1st). Patient very cheerful. Appetite good. Tonsils nearly clean; a little thin membrane on both fauces.

September 27th. Temperature: morning, 98.4°; evening, 98°. Pulse: morning, 88; evening, 96. Little membrane on fauces strongly adherent. Tonsils quite clean. Throat raw and sore, bleeding when swabbed. Patient bright and cheerful.

September 30th. Throat quite clean today for first time. Temperature subnormal. Still a trace of albumen in urine. Patient very bright and hungry, though she has taken plenty of nourishment throughout.

Remarks.—The source of infection in these cases was undoubtedly a previous fatal case which had occurred in the same house five weeks before. Case 1 sickened only five days after the family returned home from the country, and I discovered that a screen which had been used to form part of a tent-bed for the earlier case had been removed to the drawing-room without disinfection, for fear the sulphur should blacken the gilt. The sanitary arrangements of the house were very good, and, with the single exception enumerated, disinfection had been very thoroughly carried out. The cause of the earlier fatal case, I was told, could not be discovered. There were no animals kept in the house, but I do not know that the milk supply and laundry were investigated.

With regard to the effect of the antitoxin, these cases cannot be considered conclusive, as in both improvement had set in before its administration, and the same remedies were continued afterward; but the mother had no doubt as to the feeling of relief and *bien-être* which followed the injection, and the child seemed

brighter almost immediately. No local reaction took place in either case at the site of injection.

No conclusions as to dose can be deduced, as in each case I injected all I could obtain, namely, mxx. The paraffin paint seemed to directly affect the membrane, and the nurses told me that the patient used to ask for it before it was due on account of the relief afforded. No cultures were made from the throats, but cover-glass preparations from the membrane showed abundant bacilli, with streptococci, staphylococci and micrococci.

Mr. Henry G. Biddle (Broadstairs) reports a severe case of diphtheria which was successfully treated by injections of antitoxin. On July 23d I was called to see G. A., aged 34. He had complained of sore throat and had felt very ill since July 15th, and had kept to his bed since July 20th. He appeared very ill. Temperature, 101°; pulse, 130. Tongue very foul. Glands much enlarged. Tonsils greatly swollen, nearly meeting in middle line and partly covered by characteristic gray membrane. There was severe headache and the urine contained albumen. Iron and chlorate of potash was given and the fauces frequently dusted with sublimed sulphur. The following day, July 24th, the patient's condition was unchanged.

On July 25th I injected 2½ c.c. of Aronson's antitoxin solution. Temperature rose to 103° and patient became very delirious and violent toward evening.

On the 26th he was still very delirious. Temperature fell to 99° in morning, 101° in evening; 2½ c.c. of the solution injected.

On the 27th the throat was decidedly better. The membrane was beginning to get loose. He was still very delirious.

On the 28th he slept for six hours and woke up quite conscious. Temperature, 100°. Membrane coming away.

From this date the patient made an uninterrupted recovery. He got up on August 2d. Urine was then free from albumen. I have had him under my observation until the present time, and he has never had any sequelæ, no loss of knee-jerk or symptoms of nerve degeneration.

Dr. J. Grant Bride, late Medical Officer of Health, Runcorn Rural Entire District, writes:

Dr. Trevor Fowler's suggestion that the dose of antitoxin, and also that the indications for its repetition, should be definitely stated, is deserving of much attention. At the same time there would be much difficulty, I think, in finding the range and laying down rules for the employment of this recent addition to our therapeutic arsenal. It is comforting to the mind that no ill-effects have been recorded against the free use of antitoxin; therefore I would inject mv in the case of a child aged 1 year and increase it by mj for each year above that age up to 16; the dose for it and up to 20 would be mxx. In severe attacks the dose might be increased and repeated after an interval of eight to ten hours. On the other hand, good results are obtained from small doses in mild cases, but they require to be repeated, whereas a large dose (from 15 to 20 minims) did its work thoroughly without need of repetition. The following cases will support this conclusion:

Case I.—M. H., aged 64, who enjoys robust health, stout and with a florid complexion, was first seen on August 13th. She was then sallow and felt ill and exhausted. The throat was congested and painful, with a small patch of membrane on each tonsil. There was cough and difficulty in breathing. The temperature was 99.2°, the pulse 78. I ordered a mixture of perchloride of iron and chlorate of potassium and locally used salicylate of sodium.

August 14th. She had not slept much during the night. A dense membrane had covered the pharynx and fauces. The temperature at 10 A.M. was 104.2° F., at 4 P.M. 104.5°; the pulse 122. I had obtained a supply of Schering's antitoxin from Messrs. Allen & Hanburys and injected mxj. A lactic acid spray was used to the throat. She slept ten minutes after this was done and did not awake till 10.30 P.M., when her temperature was 102.8°; the pulse was 112. She had perspired very freely and now took food well; again slept until 5 A.M., took food and slept until 11 A.M. The temperature 102.3°, the pulse 100.

At 9 P.M. on August 15th the temperature was 103.2°, the pulse 126. Some fragments of membrane had been coughed up. The patient did not feel so well. Antitoxin mxvj was injected. She again slept soundly and perspired freely during the greater part of the night.

At 9 A.M. on August 16th her temper-

ature was 99.2° and at 4 P.M. 97.8°. The throat was clearing rapidly and her strength was, she declared, as good as it ever had been. Recovery went on rapidly. The urine was free from albumen.

CASE II.—D. G., aged 6 years, a delicate girl with mitral stenosis, was first seen on August 31st. The fauces and soft palate were inflamed and the tonsils and pharynx were covered with membrane. She complained of pain in swallowing. There was difficult breathing and stridor. The temperature was 104.8° F., the pulse 126 at 9 P.M., when I injected mxj of antitoxin. During the night she slept restlessly, but her breathing had become easier as the morning advanced.

September 1st. There was less stridor. The temperature was 102.4°, the pulse 114. She had taken food freely. The membrane on the palate was now curled under at its margins and had a shriveled appearance but a firm central attachment still. At 2 P.M. the temperature was 103.2°, the pulse 116. Antitoxin mxv was injected, after which she slept several hours, but was still restless.

On September 2d the temperature was 100.3° at 10 A.M., the pulse 84. Breathing was easier, stridor absent. The skin was acting freely. The membrane came away in large pieces during the day.

On September 3d the breathing again became difficult, stridor returned and the temperature rose to 102.5°. Antitoxin mxviij was injected. In ten hours the temperature had fallen to 98°, the pulse was 74. Membrane still continued to come away from the pharynx, naso-pharynx, etc., and the child continued to improve without further incident, except the presence in the urine of a small quantity of albumen.

Dr. D. Watkin Hughes (Wymondham) writes:

During the present severe epidemic of diphtheria at Barnham Broom, Norfolk, I have attended forty cases. I treated the first thirty with the usual remedies, namely, tinct. ferri sesquichl. and inhalations of sulphurous acid, iodine, carbolic acid, etc. With well-trained nurses, who most carefully attended to the patients, I lost ten out of the thirty.

For the last ten cases, some of which were very severe, I used Aronson's "Heilserum diphtheria antitoxin" (E. Schering) with marked success, injecting from mxij to xxij. The improvement was rapid and in most cases similar. On the second day after the injection the temperature rose to 103° or 104° F. On the third day it suddenly dropped to subnormal. The membrane shriveled up and peeled off in masses, leaving a raw surface, and from that time all these patients made rapid recoveries. In no case had I to repeat the injection.

The *British Medical Journal*, in the editorial notes, says:

To obtain the best results, experience already accumulated proves that the treatment must be adopted at an early stage of the disease; but at the present time, unfortunately, there is considerable difficulty in obtaining a sufficient supply of the serum. In France its preparation on a large scale has been undertaken by the Pasteur Institute, and it is hoped that in a couple of months' time the supply will be sufficient for the needs of France. The British Institute of Preventive Medicine expects shortly to be in a position to supply a considerable quantity. The treatment, however, is rapidly passing out of the experimental stage, and in the case of a disease so murderous as diphtheria, which produces annually so fearful a mortality, especially among children, the public may well look to the State to take steps to insure a constant and adequate supply of the remedy at a reasonable cost. Professor Behring, in an address before the German Naturalists' Society at Vienna, stated that in Germany and Austria alone the mortality from diphtheria might be estimated to be about 2,000,000 in every ten years. The serum treatment would reduce this high mortality, amounting to over fifty per cent. of the persons attacked, to ten per cent., and if employed in the early stage to five per cent. "In other words," he added, "about 1,500,000 lives may be saved every ten years, but of course the serum must be obtainable in large quantities. This is not now the case and will not be the case until the State takes the matter in hand and prepares it at the public cost." The mode in which the serum is obtained at the Pasteur Institute is as follows: The animals which are to furnish the antitoxic serum are rendered immune by the injection under certain precautions of the toxin of diphtheria. This toxin is formed when the virulent bacillus is grown in broth, and in practice

the rate at which it is produced is increased by drawing a current of air through the culture liquid. After three or four weeks the culture is sufficiently rich in toxin to be used. The animals employed are horses in good health and previously tested by the injection of mallein to prove that they are free from glanders. The culture, filtered through a porcelain filter, yields a clear liquid, with which the horse is inoculated by injection under the skin. Gradually, by repeated injections over a period of two or three months, the horse is brought into a condition in which its serum possesses very high antitoxic properties. The animal does not suffer in health at all, or only to a very slight degree. The efficacy of its serum having been ascertained by a test experiment on a guinea-pig, the animal is bled. It suffers little from this operation, and it is possible, if necessary, to bleed it again in two or three weeks, but it is advisable in the interval to strengthen its immunity by some further injections of the toxin. The animals used are cab horses, sound in constitution but broken down in limb, who after inoculation live a life of ease and luxury, varied by a periodical phlebotomy, such as our grandfathers submitted to voluntarily two or three times a year.

SOCIETY REPORTS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of September 26, 1894.

PROPHYLAXIS IN CHURCHES NEEDED BY THE ADOPTION OF INDIVIDUAL COMMUNION CHALICES OR CUPS.

By Dr. Howard S. Anders. See page 493 of THE MEDICAL AND SURGICAL REPORTER for October 13, 1894.

DISCUSSION.

DR. LOUIS J. LAUTENBACH: I could report a case of syphilitic retinal hemorrhage in a priest, who claims to have contracted a sore in the mouth in the manner indicated by Dr. Anders. Another similar case, concerning the origin of which the history is more clear, has occurred in my practice.

DR. WILLIAM S. STEWART: In the Catholic Church I understand that the congregation do not drink the wine, but that they eat the wafer and the priest drinks the wine.

DR. JOHN C. DA COSTA: I can sympathize with Dr. Anders, and indorse much what he has said, but question whether his ideas are practicable. Let us take a few of the leading religious bodies. In the Roman Catholic Church, I am told that the priests alone partake of the wine; if so, there is no risk of contagion and no need of more than one cup. In the Presbyterian Church the people remain in their seats, and the four elders hand around the bread and wine. Now imagine 1,000 partaking—and a separate glass for each; let each glass occupy only two inches square space, and you would need a table of 28 square feet to hold the glasses alone; or, with a Baptist church in Louisville that I know of with a communion of 2,500, a table space of 69½ square feet would be needed.

In the Episcopal Church the people kneel at the chancel rail, and the bread and wine are handed to the people by the minister. Now imagine not 1,000, but 250 separate glasses, collecting them again, and at the end draining them and himself drinking what remains, for the rubric commands that "the minister and communicants shall, after the blessing, reverently eat and drink the same" (bread and wine). It would turn a solemn ceremony into a farce.

Next, as to the risk of contagion, take the diseases in the order the doctor mentions. A person with syphilis is scarcely the one you would find going to the communion. One with diphtheria would be too sick, as would also one with tonsillitis or typhoid. Pneumonia would scarcely

be conveyed. If the doctor thinks only of unfermented grape juice, there might be some risk, but with wine such as is ordinarily used, very little, for the alcohol in the wine is in itself a good germicide.

DR. THOMAS J. MAYS: I am in sympathy with some of the suggestions of Dr. Anders. I can well see why such diseases as typhoid and typhus fever, diphtheria, syphilis, etc., may be so transmitted, but I do not believe that phthisis can be communicated in this manner. At least, before the assertions of the reader can be established, he ought to show some relation between his conclusions and his premises—that those who partake of the communion cup are more liable to phthisis than those who do not. A great deal of loose thinking is being done on this subject. I do not see why, in addition to their natural affliction, this class of sufferers should be compelled to bear the cross of a new and artificial opprobrium. They have already suffered enough. I admit that facts to prove the correctness or falsity of the position of the reader of this paper are not easy to obtain, but as possible evidence that it is not correct, I would state that it is well to remember that phthisis is more prevalent among those of our Indians who have just come in contact with our frontier civilization than it is among those who have lived a more civilized life for many years in the interior of the States of Michigan, Wisconsin, and New York. The latter being under the influence of missionaries and the Church, and observing the rites of the same, they should be more liable to this disease than the former, if the communion cup produced any special havoc in this direction, provided, of course, that other conditions are alike. I hope that Dr. Anders holds statistics by which he can prove the accuracy of his contention in this respect.

DR. JOHN AULDE: I have long been convinced that the use of the common communion cup is productive of disease. Dr. Probst, Secretary of the Ohio State Board of Health, about two years ago delivered an address to a body of clergymen, calling their attention to the unsanitary features of this practice, and the investigation at Rochester, N. Y., seems to have established the danger of the cup. If the one disease, diphtheria, can be communicated in this way, it is enough to condemn the practice without further discussion.

Dr. Thomas J. Mays read a paper on

ICE-COLD APPLICATIONS IN ACUTE PNEUMONIA.

(See page 535.)

DISCUSSION.

DR. ALFRED STENGEL: I disagree entirely from Dr. Mays as regards the heart in pneumonia. I have seen a considerable deal of pneumonia clinically, but a great deal more pathologically. I have not made a post mortem in pneumonia in which I did not find some cardiac thrombosis. I have seen the thrombosis of such a character that it was difficult to imagine how any circulation could be carried on during the last moments of life. Of course, in some cases it is difficult to determine whether the thrombi are ante mortem or post mortem, but in most cases the manifestly ante-mortem character of the thrombi shows that the heart must have been seriously embarrassed. It is certainly the opinion of most authorities that the heart is seriously embarrassed, and post-mortem experiences would indicate the same thing.

DR. J. M. ANDERS: I was somewhat astonished to hear the reader of the paper take the position that the fever in pneumonia was in all probability the result of the localized inflammation. The localized inflammation may, to some extent, show the degree of infection, but its presence does not prove that this is not an infectious disease. I should incline to the view that the temperature is an indication of the severity of the type of infection, and not of the severity of the local inflammation.

I am always glad to hear a paper on the use of cold. Cold, whether locally or generally applied, can have but one effect in this disease, and that favorable. If applied locally, as suggested, it would undoubtedly mitigate to some extent the local inflammation, but it could not in an acute infectious disease control to any extent the course of the ailment. I do not believe that there is anything that will entirely control the course and symptoms of pneumonia, simply because it is an acute, infectious, self-limited disease. The local use of cold cannot meet all the indications in a case of pneumonia. It is well enough in a mild case, where the respiration is ordinarily good, the temperature only moderately high, and there are no nervous

symptoms, but in a severe case the cold or tepid bath meets many more indications and is more efficacious. One of the reasons for the bad respiration is the presence of pain, hence this should be gotten rid of early. The local application of cold does not influence the respiration of a patient suffering with pneumonia, in my experience; whereas the cool or tepid bath stimulates to deeper respiration and assists expectoration. Its effect on the nervous system cannot be over-estimated. I shall not go into the subject in detail. It is scarcely necessary; but it is bad practice, I think, to rely upon the local use of cold, which meets but a single indication, when we have at hand the cool or tepid bath, which meets so many and such as are of vastly more importance than the mere combating of local inflammation to the welfare of the patient.

Dr. B. F. Stahl: I am interested in the use of cold in the treatment of pneumonia, and especially so after considerable experience with application of baths in the treatment of typhoid during the past few months. I recognize that the general application of cold or cool water is productive of rest and of better respiration, and it has a general tranquilizing influence by its reduction and temperature. I am led to anticipate that its application in pneumonia will be advantageous. I freely admit, however, that I have had no direct experience in the use of local application of cold in pneumonia. I am ready to try it in any case where it may be applied generally or in the form of a bath, and I believe that we may expect decided advantages from its use.

Dr. Lawrence Wolff: I have had some experience with the use of cold in pneumonia. A couple of years ago I employed the cold bath in the treatment of pneumonia in my hospital cases, but the results were not as favorable as with other methods. I have used the local application of cold with more advantage. Dr. Da Costa taught many years ago that the ice poultice was one of the best applications, and relieved pain better and stimulated respiration perhaps better than any other application. It has been productive of great good in my hands.

Dr. John Aulde: My object in speaking is rather to make a suggestion to the reader of the paper in order to establish some physiological basis which may be of further value as indicating the effect which cold applications produce in pneumonia. The empirical deduction as to the value of ice in pneumonia seems to be fairly well founded, and would have been accepted ten or five years ago as very good evidence, but at the present time it seems to me that something more is demanded. It is hardly worth while nowadays to speak of "vital force," because we can go closer to life than that term would indicate.

The use of the cold bath in typhoid fever has been referred to and its virtues highly lauded. If the cold bath is useful in typhoid fever we should be able to make some observations which would give us some exact idea of the effect which it produces. It would surprise you if I were to prophesy that within two or three years some one would come before this society and advocate the use of massage in the treatment of pneumonia. It is only a few months since that a paper was published by Dr. Mitchell, of this city, referring to the wonderful effect of massage in anæmia, showing that it increased the number of red and white corpuscles.

In pneumonia we have rather a peculiar condition, different from that seen in typhoid fever. Dr. Osler has made some observations on the changes in the blood in this disease. He found that shortly after the leucocytes began to increase in number there was a defervescence, and a favorable change took place. If the number of leucocytes is large, that is, if a general leucocytosis takes place, he is able to say that the patient will recover, even if the temperature has not changed. In typhoid fever there is no leucocytosis, but it seems probable that in typhoid fever the cold bath is sufficient to produce an artificial leucocytosis. Consequently, if the cold bath is valuable in that disease it seems probable that it may produce the same effect in pneumonia, where there is a natural tendency to leucocytosis.

I would suggest that the blood be examined in cases where ice is applied. If it can be shown that the effect of cold is to increase the number of leucocytes, we shall have a definite basis on which to rest our conclusions.

The President, Dr. De Forest Willard: I would ask Dr. Aulde if Dr. Mitchell did not subsequently explain the increase in the number of corpuscles found, not by an actual increase in the

number of blood-disks, but by the fact that corpuscles lurking along the circumference of the vessels were brought into the current by the massage, just as the logs along the banks of a lumbering stream may be forced into the current?

DR. AULDE: Of course, we are not assuming that there is an increase in the number of corpuscles *de novo*. If those out of the current are brought into the stream by the contraction of the vessels, it is substantially the same thing. This brings out the leucocytes that are instrumental in maintaining the antiseptic condition of the blood, and with the contraction of the blood-vessels, produced by the cold, the red corpuscles carry oxygen to the tissues and take away carbonic acid and other waste products.

DR. MAYS: Dr. Aulde seems to lay great stress on the fact that leucocytes are present in pneumonia. Leucocytosis is present in many conditions, both normal and pathological. Every time you take a drink of beer, or eat a beefsteak, or take bitters, leucocytogenesis is increased. I do not think that the fact that the number of leucocytes is increased is of any great advantage in the successful treatment of pneumonia.

Dr. Stengel referred to the presence of thrombi in the pulmonary blood-vessels of pneumonia, and I think I must have read my paper to poor advantage if I have not succeeded in making plain my belief in the existence of this condition. Indeed, I invoke the high authority of Dr. Fox to show this. I think my intention has been misconceived by Dr. Stengel. The point that I tried to make clear was that this thrombosis leads many practitioners to try to whip up the heart to perform the impossible task of pumping blood through this thrombotic condition of the vessels in the lungs. They lose sight of the fact that the foundation of this thrombosis exists primarily in the lungs. They do not pay any attention to its removal in their treatment. The patient dies, and they believe that he dies because the heart has failed to perform its duty, while in truth death is caused by pulmonary failure.

I know that Dr. Anders has made use of cold, and I think that his results were rather favorable. He speaks of the fever as an indication of the extent of the infection. If by infection he means the amount of disease in the lung, I can hardly indorse the statement. I have in some of my cases seen high fever where there was small amount of infiltration. In one case particularly, seen three years ago, the amount of infiltration at the base of one lung was so slight as to be detected with difficulty, yet the patient had a temperature of 106° and 106.5°, and died in eight days. I did not apply ice in that case, for I did not then know its great value. I wish that I had, for I believe I would have saved the life of a dear friend. I infer from what Dr. Anders has said that he has not applied ice assiduously and persistently, for had he done so I think that he would not have said that he could not control the respiration in pneumonia by the application of cold. I expect in every case where ice is applied to have the temperature fall, the pulse fall, and the respirations fall. I do not think that the use of tepid or even cold baths is of service in pneumonia. The fever in pneumonia is different from that in typhoid fever. It does not yield to general cold as does the fever in typhoid. I think that if the prejudice against the application of ice would be removed, this treatment would be more thoroughly tried. I think that it will be found to be the most applicable and efficacious treatment for pneumonia. This has not only been my experience, but also that of others. It has been almost universally successful; in seventy-four cases there having been only two deaths. I do not say that this proportion will be maintained, but the treatment certainly has a great influence upon the local process in the lung. It circumscribes and aborts the exudation in the lung, and this is as much as can be expected from any measure.

Dr. Louis J. Lautenbach read an article entitled

MASSAGE VERSUS REMOVAL OF THE SOUND-CONDUCTING APPARATUS IN NON-SUPPURATIVE CASES OF DISEASE OF THE EAR.

(See page 538.)

DISCUSSION.

DR. L. J. HAMMOND: The experience of Dr. Lautenbach does not accord with that of Drs. Knapp and Dench, of New York, as given at the meeting in Washington. They seemed to think that the massage treatment did not give the results that

were expected from it. The experience of these and other gentlemen has been that where there is a marked retraction with great thickening, the results are not as good as those obtained by the ordinary methods with the Politzer bag and Siegle speculum. The cases that were at all benefited were the mild ones, that would have shown the same result by the routine treatment.

Dr. Lautenbach laid great stress upon the bones as a conducting medium. There have been a number of cases where the malleus and incus have been entirely destroyed with the membrane, and yet hearing was perfect. I recall three such cases. I think that the bones as a whole have very little to do with hearing, except the stapes. I think that the healing depends largely upon the condition of the footplate of the stapes over the oval window. If that be markedly bound down, I do not see how massage alone will be of great value. When added to the general routine treatment it may serve a good purpose.

Reference was made to permanent paralysis following operative treatment. I have done the operation many times, principally for suppurative conditions, and have had temporary paralysis only follow. All operations involving the tympanic attic have been followed by temporary paralysis, and the general opinion is that it is impossible to prevent it in these operations, owing to the close proximity of the facial nerve. It, however, invariably subsides without treatment in a few weeks.

Dr. E. Larue Vansant: I have had considerable experience with this massage, and in non-suppurative cases have been fairly well pleased with it. Certain cases, however, are not improved, and this may be explained by the pathological condition present. Where the adhesions are not great the case will improve. It may truly be said that they improve almost as well under the use of the catheter and Politzer bag. Where there are marked adhesions binding the drum-head down to the promontory, and probably adhesions between the ossicles, the massage treatment will not break these adhesions, and may not even stretch them. What it will do will be to puff out that part of the membrane not bound down by the adhesions. I have for some time made use of Delstanche masseur and with it used Siegle's speculum, and in this way I can easily see when by increased pressure certain parts of the membrane are made to bulge. Indeed, you can almost at once give a prognosis as to whether or not massage will do good.

In non-suppurative cases I think that it is not wise to recommend removal of the drum-head and ossicles for the permanent improvement of hearing. For the intense tinnitus or vertigo it may be recommended in certain cases. It is more preferable than massage for intense tinnitus with vertigo. Lately I have been treating these cases of non-suppurative otitis media with marked retraction by a combination method. I have first made an incision in the drum-head, and then, taking the little trowel-shaped knife used in removing the ossicles, have attempted to cut through some of the bands in the middle ear, particularly toward the promontory, and then followed this treatment by massage so as to prevent the re-formation of adhesions while healing is going on. I think that my results have been better than with either method alone.

Dr. George C. Stout: I think that massage and treatment of that kind should be instituted before any operation is recommended and that this is the general practice. Operation should be reserved for a last resort, and, so far as I can learn, this is the rule with all modern aurists.

The instruments which make a noise synchronous with the massage are as yet considered a doubtful improvement over noiseless massage.

Dr. Lautenbach: I am glad to learn that so many have used massage, but unfortunately most of the methods in use have been crude. I have used Siegle's speculum as a masseur for thirteen years; but this is not the method that I referred to in my paper. I refer to regular massage, with a definite amount of exhaust used, a definite number of times a minute, studying your case until you find the amount of motion that you desire, and regulating it accordingly. When Dr. Knapp and Dr. Dench referred to massage they could not have spoken of this method, as they knew not of its use. They have to-day no such instrument in their offices. I understand they both have the vibrometer and the vibrophone, but not this machine. The methods in use outside of the Siegle speculum and the Delstanche apparatus have been methods of phono-massage and not pneumo-mas-

sage. The phono-massage methods have their use not so much in the process of loosening up the sound-conducting apparatus as in stimulating that part of the nervous structures of the labyrinth lying close to the stapes. We are now learning that in plastic and catarrhal disease of the middle ear, the proximal endings of the auditory curve—those nearest the stapes—are affected often early in the disease. Often even when the hearing to the watch is quite good the patient has tinnitus. This indicates that the labyrinthine structures have been affected early. In those cases where there is loss of hearing without tinnitus, phono-massage will be of no service. The main advantage to be derived from phono-massage is in the dissipation of tinnitus. It cannot restore the lost hearing.

Speaking of the necessity of a sound-conducting apparatus, I think that it is a self-evident proposition that the sound-conducting apparatus so carefully constructed and mechanically so perfect would not be there if it were not needed. I do not think that it would have received so much attention from Helmholtz if it did not have its use. I admit that I have taken out the stirrup, and the patient could still hear; but I also know that the patient did not hear perfectly.

I do not mean to advocate massage separate from all other treatment of the ear. I do not think that any case of ear disease is to be treated by massage alone. In my paper I presumed that all other necessary treatment would be thoroughly carried out. One who tries to treat disease by one method without paying attention to the general as well as the local conditions present utterly fails to comprehend the science of medicine.

Speaking of severe cases, I might refer to a lady, aged thirty-four years, a school-teacher, who since early childhood has been deficient in hearing. For eleven or twelve years she has been constantly under treatment and constantly getting worse. Five or six weeks ago a physician advised her that an ossicle operation was the only thing to be done. Another physician expressed the same opinion. I saw her Monday two weeks ago, and since then she has been treated in the ordinary way and with powerful pneumo-massage to the ear. This morning she told me that she could hear her clock at two or three inches from the to-be-operated ear, a thing that she has not done for six years. In the ear the membrane is adherent to the promontory, but has been detached mechanically by the two weeks' treatment.

The massage method does separate the drum-head from the promontory, and it is only a question of time when the adhesions will be removed. The Delstanche masseur, while a good instrument in its way, is not the one that I should prefer in these cases. You cannot get with it the precision of motion and persistency that you desire. You cannot if necessary keep it up for one hour at a time. You want a method that will give you an easily regulated persistent movement of the ossicles and be able to use it as long as you desire, anywhere from five minutes to an hour or even more.

The Early Diagnosis of Phthisis.

In a paper read at the International Congress, M. Bernheim, of Paris, calls attention to the following points, which may be advantageously made use of in addition to the usual clinical symptoms of beginning pulmonary tuberculosis: "1. The examination of the secretions (urine, excess of phosphates and diminution of urea; blood, changes in configuration of the corpuscles; expectoration, presence [rare] of bacilli; urine ditto). 2. The inoculation of the patient's blood into an animal. 3. The examination of the lymphatic system (in many cases of commencing phthisis the glands are enlarged). 4. The constant hypertrophy of the spleen. 5. The improvement induced by the inoculation of these *débutants* in phthisis with immunized serum, the condition of other patients not being ameliorated by serotherapy. Of course, the association of several of the above signs is necessary before the diagnosis can be affirmed; but the early and constant enlargement of the spleen is a sign to which attention has not been called sufficiently, and on that ground I deem it worthy of mention to-day."—*Indian Medical Record.*

Doctor—A careful diagnosis of your case leaves no doubt that you have stone in the bladder.

Solomon Isaacstein—Doctor, do you tinks it vas a diamont?

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

BUFFALO MEDICAL AND SURGICAL JOURNAL for October. Dr. Wm. C. Krauss discusses the

"Treatment of Neurasthenia."

He gives among the prominent symptoms of this disorder: Moroseness, fault finding, dull aching in the occiput or at the vertex, and in the lumbar spinal region. Following these come tachycardia and palpitation, sinking spells, hot flushes, profuse perspirations on the face and extremities, indigestion, short attacks of jaundice, scanty secretion of urine of high specific gravity, temporary sexual impotence. Great stress is laid on the appearance in all cases, with vasomotor symptoms, of a dilatation of one pupil with a contracture of its fellow. The author thinks this due to derangement of the sympathetic nerve.

For treatment the cases are subdivided into (1) those with a lithæmic element; (2) those without a lithæmic element; (3) those with marked vasomotor disturbance.

After trying to find and remove the cause of the disorder the asthenic cases of the first two divisions are ordered to take, before rising, two ounces of strong, black coffee, and in a half hour take a tepid sponge bath for about five minutes, then dress and take breakfast. The plethoric cases receive, instead of this, one-half ounce or one ounce of a saline cathartic followed by a cold bath, and if possible a cold plunge. Just before retiring a warm general bath is taken.

For from five to eight minutes a galvanic current is applied with the electrodes on the sacrum and the neck, then the positive pole is applied to the forehead and a weaker current turned on, and, finally, with the electrodes to the hands as strong a faradic current is applied as the patient can bear. This treatment is given once, twice, or thrice weekly; the severe cases receiving treatment three times weekly.

Massage may be given also, and the lithæmic cases receive after meals one to three tablets, each containing lithium carbonate, 3 grains; phosphate of iron, ⅓ grain; extract of nux vomica, 1-9 grain; arseniate of soda, 1-27 grain. The author claims that patients who seem unable to take iron in other forms use this tablet with benefit and that it acts well also in cases of chronic rheumatism.

Non-lithæmic cases are given bromides, hyoscyamus, tincture of nux vomica, albuminate of iron, phosphoric acid and pepsin. Trional in five or ten grain doses is the favorite hypnotic.

Cases with vasomotor disturbances have been intractable and unsatisfactory.

Dr. Frank J. Thornbury describes some

Interesting Dermatological Cases

seen in Kaposi's clinic.

A number of diseases rarely recognized elsewhere, if seen, are not uncommon; prurigo is one of these.

The first case reported was a man who developed pemphigus while under treatment for lichen ruber planus. There is said to be no similar case on record.

One or more cases of pemphigus may always be found in the wards. The treatment includes a water bath of from two to five hours daily, the treatment of Hebra for variola.

A disease more common in Austria-Hungary than elsewhere is rhinoscleroma. This commences on the mucous membrane near the ala nasi and slowly extends until the pharynx is involved. Cellular infiltration with increased vascularity takes place, and owing to increase of connective tissue the part becomes pale and hard and the function is interfered with.

Contraction of the nostrils and involvement of the larynx cause snoring and give the voice a harsh, nasal sound. A case may continue for ten or twenty years.

The bacillic cause of this disease has been isolated, but no known treatment is very effective.

A well marked case of ichthyosis hystrix was seen, in which the patient was so covered with horny spines as to resemble a porcupine.

Another peculiar case was one of psoriasis, in which the interpapillary hypertrophy had gone to such an extent as to cause homors varying in size from that of an almond to that of a walnut. These subsided promptly under doses of arsenic.

Kaposi's favorite local application is a ten per cent. solution of gallacetophenone, and this is painted every few days over the affected areas only.

Kaposi, the author says, treats all new cases of lupus and all newly affected areas of old cases by a thorough scraping with the sharp spoon; sometimes using cocaine, sometimes not. Some cauterizant, such as pyrogallol ointment, is then applied. Pick, of Prague, on the contrary, uses with uniform success an injection of about 1-130 grain of tuberculin. This results in a breaking down of the affected tissue and healing by granulation.

A translation by Mr. L. G. Sellstedt of an article by Dr. E. S. Perman on Stygiea describes a case of

Sarcoma of the Tongue Treated With Pyokotanin.

The growth involved more than half of the root of the tongue, was increasing in size, and caused considerable discomfort. Excision of the tongue was refused, so a preliminary tracheotomy was done, and subsequently injections of one to two grammes of a 1-500 solution of pyokotanin were made into the tissue near the growth.

After five injections the growth appeared

diminished, and later the pedunculated portion was excised by galvano-cautery, and the next day a small mass was found to have sprung up at one side and finally this also was excised.

The treatment during this time was continued, and up to the present time (the latter part of April) no return of the disease was apparent.

Other papers in this issue are "The Causes of Hernia With a New Theory," by Dr. Byron Robinson; "Hypertrophy of the Follicular Glands at the Base of the Tongue," by Dr. Horace Clark.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE

Veratrum Viride in Catarrhal Pneumonia in Children.

Dr. F. B. Sutliff, Sacramento, Cal., says, in a paper read before the Sacramento Society for Medical Improvement, after reviewing the treatment of prominent writers, that he thinks there is no remedy that is more of a specific for any disease than veratrum viride in catarrhal pneumonia in children. He does not believe veratrum viride has anything like the same influence on other forms of pneumonia, and thinks to this is probably due the fact that it has at times received such unlimited praise, and at others such condemnation.

The tincture is given in small (a fraction of a minim) and oft repeated doses until the pulse is reduced and respiration is lowered.

The following case is reported: Child two years old with breathing about sixty per minute; pulse very fast; cannot sleep nor rest on account of constant cough. Has been sick for one night only, but there were coarse rales over both lungs. He was getting blue and the case looked like a bad one. Ordered half-minim doses of tincture of veratrum viride combined with sweet spirits of niter and syrup yerba santa, the dose to be repeated hourly. In a few hours the good effect was manifest, in twelve hours the child was very much better, and the next day it had changed to an ordinary case and soon went on to convalescence.—*Denver Medical Times.*

Indicanuria as a Symptom of Latent Suppuration.

Indican, in small quantities, is a normal constituent of healthy urine, but under certain circumstances the amount is so large as to merit the designation of indicanuria. This condition is usually dependent on decomposition of the intestinal contents consequent on constipation; but it has recently been discovered in the urine in connection with the formation of pus in such quantities as to authorize the belief that its presence may afford an important indication of latent suppuration. The first thing, of course, is to eliminate the intestinal tract as the source of the indicanuria, and this is done by the administration of naphthol, bismuth, or other disinfectant. Should chemical analysis still reveal the persistence of the indicanuria, there is reason to suspect suppuration. In several cases observed by Dr. Keilmann, of Dorpat, the information thus obtained led to a successful search being made for foci of suppuration, the indicanuria subsiding as soon as the pus was evacuated. The analysis is simple enough to admit of its application by every one, which is more than can be affirmed of many of the tests proposed by laboratory physiologists. Equal quantities of urine and strong hydrochloric acid are shaken together in a test-tube, and a little chloroform is added. In the presence of indican this becomes blue from the indigo liberated by the decomposition of the indican, and falls to the bottom of the tube. A fair idea can thus be readily obtained of the amount of indican present, but for the purposes of diagnosis it is necessary to resort to a quantitative analysis. This does not involve much additional trouble, advantage being taken of the bleaching powers of hypochlorite of calcium, a standardized solution of this salt being dropped into the above mixture until complete decoloration results. Three or four drops of a five per cent. solution may suffice for this purpose, but in some cases as much as fifty, or even eighty, drops may be required.—*Medical Press and Circular.*

The Falkenstein Treatment of Pulmonary Tuberculosis.

We hear a good deal about the open-air treatment of pulmonary tuberculosis, and the attempts to raise this method into a "system," as practiced at Falkenstein, in the Taunus Mountains in Germany, are worthy of all praise, so far as they demonstrate to the world at large—which is not very believing in such matters—that tuberculous patients are all the better for open windows. At the establishments at Falkenstein, in addition to good food, cleanliness, perfect sanitation and most careful measures to prevent the diffusion of tuberculous dust, a definite attempt is made to enable the patients to pass their whole time in the open air. Plenty of rugs and clothing are allowed, and the rooms and corridors are plentifully supplied with heating apparatus; but, except when actually dressing or undressing, the windows of the bedrooms must be open day and night, in all weathers and in all seasons, and during the day the

patients dwell in the corridors or summer-houses or altogether out of doors. The results are said to be satisfactory. One point is of much interest. The number of patients whom it is necessary to confine to their rooms hardly varies in the different seasons, being 8.5 per cent. in the summer and 9.33 per cent. in the winter months. It seems clear, however, that a treatment of this sort, if useful at a health resort, should be equally applicable to home life, and that the lessons taught by it are as important to the healthy as to the sick. If these delicate poitrinaires can bear open windows and fresh air, so can people in ordinary health, and there can be no doubt that people would be better off in every way if they very much lessened the difference between indoors and outdoors as regards both clothing and fresh air. The lesson to be learned, however, from the Falkenstein treatment is that a certain acclimatization is required, and that what is begun must be persisted in. A man who sleeps with open windows one week and shuts them the next is sure to suffer from disorders of the air-passages.—*Medical News.*

Consumption at Different Ages.

The common impression based on the statements of many of the older text-books is that phthisis is especially a disease of early adult life. The statistics of death in Great Britain, probably the most complete and extensive anywhere attainable, however, indicate that this is not correct. The largest number of deaths, according to these statistics, occur in the decade from thirty-five to forty-five years of age, and that not until about sixty years of age do the number of deaths from this cause, as compared with the number of persons living, fall below the average for the period, from twenty to twenty-five. It is to be remembered, however, that the disease usually requires several years to run its course, so that infection probably occurs on the average nearly five years earlier than death.—*Phila. Polyclinic.*

The Action of Asparagus on the Kidney.

Three years ago Wilks sent a short communication to the *Lancet*, requesting the opinion of the profession on this subject. He therein stated that, in spite of books declaring asparagus to be a diuretic, he had observed that the very contrary was its action. Four letters came in reply, written by medical men. Three of them stated that from direct observation they had ascertained the inhibitory action of asparagus on the function of the kidneys, so that frequently only a third of the normal quantity of urine was secreted after eating this vegetable. The fourth gentleman said he had no knowledge of his own, but believed asparagus to be a diuretic, as he had always understood it to be so. The question of this vegetable's action in the economy is of little importance when it is so universally eaten and approved of, but it is one of interest in connection with the history of medicine as a science and art. In other sciences knowledge has grown from small beginnings, so that they have a solid foundation and superstructure; but the practice of medicine has existed from the remotest ages and was born of superstition. Consequently, a large part of our advance has been by getting rid of and overthrowing error. The writer has on his shelves a "Herbal," published about a hundred years ago, describing the value of a vast number of plants which are now discarded as useless; but that a positive error, and one the very reverse of the truth, as regards the action of a well-known vegetable should still be propagated in books is a most remarkable fact and, as regards the whole subject of therapeutics, a very sad one. —*Lancet.*

Fournier-Syphilis in Childhood.

Most physicians and all of the laity hold the erroneous idea that syphilis in the child is always hereditary and very seldom acquired. Two points must be understood: (1) Syphilis is never acquired during childbirth, because at birth the child is already syphilitic. (2) An acquired syphilis is never dependent upon syphilis of the mother which she acquired before the child's birth, for here, again, the child is born syphilitic, although it may be latent. The positive causes of contagion are thus reduced to—

1. Nursing, by which a previously syphilitic nurse infects when she develops patches in her mouth or papules upon the nipple, or by a nurse who is herself infected by nursing a second and syphilitic child.
2. During its growth; by its mother, subsequently affected; by its father, by its attendant, especially by kissing; by other persons with whom it comes in contact.
3. Criminal attempts.
4. Inoculation by physicians or midwives, either by the hands or by instruments.

Fournier concludes that children acquire syphilis more often than is supposed.—*New York Polyclinic.*

A HUMOROUS letter in the *American Practitioner and News* cast deserved ridicule upon the animal extracts so widely advertised in the daily press, and which, to the shame of the profession, have attached to them the name of a widely known physician. The writer of the letter details his experimental attempts to grow new parts upon mutilated dogs, using for the purpose extracts from the ears, tails, legs, noses, etc., of other dogs under the names of "earine," "tailine," "legine," "nosine," and the like. By an unfortunate mixing up of the extracts he grew legs and tails of entirely different breeds from the rest of the dog with most confounding and embarrassing results, and he warns future experimenters in this line to beware of his mistakes or they may find some day that they have caused the flat nose of a full-blooded negro to grow upon some blond young lady, who might cause them to be mulcted in enormous damages in consequence of so disastrous a blunder.

Typhoid Fever in Infancy.

Noyes (*Med. Rec.*) reports eight cases occurring in children from eleven months to three years of age, in a recent epidemic due to a contaminated milk supply. He thinks any long-continued fever, without obvious local inflammatory cause, suspicious, especially if joined with gastro-intestinal disorder; and the rose spots should be carefully looked for and the stools examined for characteristic bacilli. He urges the sterilization of all milk used for young children, and the disinfection of the stools in all cases of diarrheal nature. —*Polyclinic.*

SURGERY.

Internal Hemorrhoids.

Dundore (*Mathews's Medical Quarterly*), after an exhaustive paper on this subject, concludes as follows:

1. The ligature is the safest method of operating for internal hemorrhoids, as there is less likelihood of its use being followed by hemorrhage, stricture, or ulcers.

2. The clamp and cautery cause less pain, shorter convalescence, and are less likely to be followed by retention of urine than when the ligature is used; but hemorrhage and stricture of the rectum may very often follow their improper application.

3. The practice of Whitehead's method should be limited to those cases in which the entire circumference of the anus is involved. In ordinary cases of one or more hemorrhoids it should never be used, as it is liable to be followed by severe after-effects, and at best could produce no more radical result than the clamp and cautery or ligature.

4. Simple dilatation of the sphincter, injection of carbolic acid, and Manley's method are simple palliatives, and their use is very limited.

5. There is no single operation which is available in all cases. Experience alone should suggest the most efficient method of treating each individual case.—*Therapeutic Gazette.*

BACTERIOLOGY.

Oxalic Acid as a Germicide.

Potassium permanganate has long been reputed a reliable germicide in practical surgical work; and at the Johns Hopkins Hospital the routine preparation of the surgeons' hands was, after thorough washing, to have them immersed in a solution of permanganate until stained a deep red-brown. To remove the stain, they were then placed in a warm saturated solution of oxalic acid. Repeated bacteriological tests have shown that this method was very effective.

A series of experiments by Dr. Mary Sherwood (*Johns Hopkins Hospital Reports*) to test the relative germicidal powers of the two solutions, however, seems to indicate that the real germicide was the solution of oxalic acid. Using bits of surgeon's silk, dipped in cultures of *staphylococcus pyogenes*, it was found that potassium permanganate in saturated solutions did not sterilize them, either at the room temperature or at a temperature of 45° C., by exposure of from one to ten minutes. On the other hand, oxalic acid in saturated solution, at a temperature of 40° C. to 45° C., sterilized the infected threads exposed to its action for one minute, showing the oxalic acid to be the more powerful germicide.—*Polyclinic.*

OPHTHALMOLOGY.

Injury to the Eyes from a Heavy Charge of Electricity.

Rivers (*Archives of Ophthalmology*) reports the case of a man, aged 25, who received an electrical force amounting to 550 volts; the discharge of the electrical force issued from a wrench, which was on a level with his face, a loud report occurred and an intense flash of light. The patient was knocked down; vision was immediately affected; the eyelashes and eyebrows were nearly burned off, the ocular conjunctiva had the appearance as if it had been painted with a strong solution of nitrate of silver, the cornea in each eye was of the appearance of ground glass, the opaqueness being greatest at the center, vision equal to perception of light. Eleven days later there was no corneal opacity, and the vision of the right eye equaled 20–CC, and the left 20–XL. The ophthalmoscope showed the media perfectly clear, the optic discs and retinal vessels looked normal. Vision gradually improved to $\frac{20}{20}$, although photophobia was marked, and he has to wear smoked glasses when out of doors.—*Medico-Surg. Magazine.*

PATHOLOGY.

A Nomenclature for the Different Classes of Infectious Diseases.

The following classification of infectious diseases was submitted by Dr. Thomson for the consideration of the New York Academy of Medicine at its meeting held May 3, 1894, with the hope that it would serve to invite discussion on a subject of great public importance, namely, the adoption by the profession of a definite nomenclature descriptive of the various classes of infectious diseases.

1. All infectious diseases are due to the presence of their specific living micro-organisms in the body.

2. Infectious diseases are divisible into three classes, (1) the communicable, (2) the non-communicable, and (3) the septic.

3. The communicable diseases are those whose origin is from an animal body. Examples are small-pox, Asiatic cholera and tuberculosis.

4. The non-communicable infectious diseases are those whose origin is not from an animal body, but from a place or thing, examples of which are ague, yellow fever and miasmatic diseases in general.

5. The communicable diseases are divisible

into two classes, according to the ordinary modes of their communication, (1) into the contagious and (2) into the non-contagious communicable diseases. The contagious communicable diseases are those in which simple proximity to the infected with them is sufficient to communicate the infection to those susceptible to them, examples of which are typhus fever, scarlet fever, small-pox, measles, diphtheria, mumps, whooping-cough, etc. Isolation of the sick with them, therefore, is needful to prevent infection.

The non-contagious communicable diseases are those in which the communication is not by simple proximity to the sick, but through intermediate means of communication. Isolation of the sick with them, therefore, is neither needful nor effective, in comparison with measures directed against the intermediate means of the infection. Examples of these diseases are typhoid fever, Asiatic cholera and tuberculosis.

6. The septic infectious diseases are those in which the infection has gained entrance through a wound, or damage, by inflammation or otherwise, of the skin or of a mucous membrane. Examples of these are surgical infection of wounds, erysipelas, hydrophobia, tetanus, etc.

Lastly, all infectious diseases can be prevented by measures of disinfection applicable to each.—*Medical Record.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM OCTOBER 7, 1894, TO OCTOBER 13, 1894.

Upon abandonment of Mount Vernon Barracks, Alabama, Major Curtis E. Munn, Surgeon, is ordered to Benicia Barracks, California, relieving Captain Ogden Rafferty, Assistant Surgeon.

Captain Rafferty, on being relieved by Major Munn, is ordered to Presidio of San Francisco, California, for duty.

First Lieutenant Charles E. B. Flagg, Assistant Surgeon, relieved from duty at Presidio of San Francisco, California, and ordered to Angel Island, Cal., for duty.

Major Van Buren Hubbard, Surgeon, relieved from duty at Fort Spokane, Washington, and ordered to Fort McPherson, Georgia, for duty at that station.

Upon arrival of Major Joseph K. Corson, Surgeon, at Fort D. A. Russell, Wyoming, First Lieutenant George D. DeShon, Assistant Surgeon, will be relieved and ordered to Fort Logan, Colorado, for duty.

Upon abandonment of Fort Sully, South Dakota, Captain Alfred E. Bradley, Assistant Surgeon, is ordered to Fort Keogh, Montana, for duty.

Upon abandonment of Fort McKinney, Wyoming, First Lieutenant Henry A. Shaw, Assistant Surgeon, is ordered to Fort Niobrara, Nebraska, for duty.

Upon abandonment of Fort Bowie, Arizona, Captain Jefferson D. Poindexter, Assistant Surgeon, is ordered to Fort Riley, Kansas, for duty.

Upon abandonment of Fort Marcy, New Mexico, Major James F. Kimball, Surgeon, is ordered to Fort Wingate, New Mexico, for duty.

Upon arrival of Major Kimball at Fort Wingate, Captain C. N. B. Macauley, Assistant Surgeon, will take station at Fort Apache, Arizona, for duty, relieving Lieutenant M. W. Ireland, Assistant Surgeon.

Lieutenant Ireland, on thus being relieved, will take station at Fort Stanton, New Mexico, relieving First Lieutenant F. R. Keefer, Assistant Surgeon.

Lieutenant Keefer, on being relieved, will proceed to and take station at Washington Barracks, District of Columbia.

Upon abandonment of Fort Supply, Oklahoma Territory, Major Curtis E. Price, Surgeon, will proceed to and take station at Fort Sill, Oklahoma Territory.

First Lieutenant Isaac P. Ware, Assistant Surgeon, is relieved from duty at Fort Supply, Oklahoma Territory, and ordered to Camp Eagle Pass, Texas, for duty.

Upon arrival of Lieutenant Ware at Camp Eagle Pass, First Lieutenant Alexander N. Stark, Assistant Surgeon, will return to his proper station at Fort Sam Houston, Texas.

Upon abandonment of Fort Mackinac, Michigan, Captain E. F. Gardner, Assistant Surgeon, is ordered to Boston, Mass., for duty as attending surgeon and examiner of recruits, relieving Major M. W. Wood, Surgeon, who, on being thus relieved, will proceed to take station at Boise Barracks, Idaho, to relieve Captain William Stephenson, Assistant Surgeon.

Captain Stephenson, Assistant Surgeon, on being relieved, will proceed to and take station at Vancouver Barracks, Washington.

By direction of the Secretary of War, leave of absence for twenty-five days, to take effect upon his relief from duty in Boston, Mass., is granted Major Marshall W. Wood, Surgeon.

By direction of the Secretary of War, Captain Francis J. Ives, Assistant Surgeon, having proceeded with troops to Fort Ethan Allen, Vermont, is relieved from further duty at Fort Sheridan, Illinois, and will remain on duty at Fort Ethan Allen until the arrival thereat of Captain Aaron H. Appel, Assistant Surgeon, when he will report in person to the commanding officer Plattsburgh Barracks, New York, under the requirements of par. 10, S. O. 24, A. G. O., September 20, 1894.

By direction of the Acting Secretary of War, Captain George E. Bushnell, Assistant Surgeon, will be relieved from duty at David's Island, New York, by the commanding officer of that post on the receipt by him of this order, and will then report in person to the commanding officer Fort Hamilton, New York, for duty at that post, reporting by letter to the commanding general Department of the East.

By direction of the Acting Secretary of War, the extension of leave of absence granted Captain C. N. B. Macauley, Assistant Surgeon, in S. O. 55, Department of the Colorado, September 14, 1894, is further extended one month.

ORIGINAL ARTICLES.

OCULAR HEADACHE.

ANNA C. HANDS, M.D., Boston, Mass.

Ocular headache may be defined as pain or distress in the cranium and face, which is the reflex expression of some abnormality in the visual organs or in the performance of their function. Oculists had long been familiar with the fact that disorders of the refractive apparatus of the eye would occasion cerebral discomfort and pain, but it had not occurred to physicians to look for eye defects to explain headaches whose origin was obscure, until S. Weir Mitchell brought the subject prominently forward in The Medical and Surgical Reporter, August, 1874, and later in the *Amer. Jour. of the Med. Sci.*, April, 1876.

The points made by him were:

1. That many headaches are caused indirectly by defects of refraction or accommodation.

2. That in these instances the brain symptom is often the only prominent indication of the eye trouble, so that there may be no ocular pain, but the eye strain is expressed solely by frontal or occipital headache.

3. That long-standing eye troubles may be the unsuspected cause of nausea, vertigo and insomnia.

4. That in many cases the eye trouble becomes suddenly injurious, owing to a breakdown in the general health or to increased sensitiveness of the brain from mental or moral causes.

The knowledge is now so universally accepted that the writers upon the subject are legion.

Bickerton found headache a distinct symptom in 277 cases out of 1,000 in which refractive errors existed.

Ranney describes cases of sick headache relieved by correction of eye strain, and says: "I have yet to meet a case of typical migraine in which a marked error of refraction or a serious muscular anomaly in the orbit did not exist." He also concludes that there is a relationship between anomalies of visual apparatus and the neuropathic tendency; proving by records that eye defects are found in a large proportion of these subjects, many of them congenital and inherited. That chorea, epilepsy and insanity even have been cured by remedying ametropia and muscular deficiencies is abundantly substantiated by many good authorities.

Charcot finds ophthalmic migraine divisible into two classes:

1. Simple, manifested by headache and visual disturbances; and

2. Concomitant, with aphasic, sensory and motor disturbances in addition.

Stevens has arrived at the following conclusion: "Difficulties attending the functions of accommodation and of adjusting the eyes in the act of vision, or irritations arising from nerves involved in these processes, are among the most prolific sources of nervous disturbances, and more frequently than any other condi-

tion they constitute a neuropathic tendency."

The study of the nervous supply of the eye and of its intimate connection with that of surrounding structures makes the phenomena of reflex headache seem very reasonable, when we remember that an irritation set up in any nerve gives rise to the greatest variety of disturbances in any or all the other parts of the organism. Six of the twelve pairs of cranial nerves send branches to the organ, and the second, third, fourth and sixth are distributed to it exclusively, and there is a still further supply by twigs from the cervical and cerebral sympathetic nerves. The retina and optic nerves originate as buds from the anterior cerebral vesicle, and retain respectively the structure of a ganglion and of a cerebral commissure. There is an exceedingly intimate connection between the blood and lymph circulations of the eye and of the cerebrum; therefore it is not to be wondered at that the visual organs frequently become delicate exponents of intra-cranial changes.

In accordance with these facts, it may be stated as an axiom that it is imperative in all cases of cerebral disease to examine the interior of the eye with an ophthalmoscope, even if the patient declares his sight perfect and that he can read small type readily. It is in this examination alone that we can see a living nerve and observe the vascular and nervous changes going on, which are a picture in miniature of the condition of the brain itself. In the emmetropic eye, distant vision is accomplished without any effort of the ciliary muscle; but in the hypermetropic eye the accommodation must be brought into use to bring even the parallel rays to a focus on the retina, and of course for all near work a much greater effort is required.

It is thus a fact that the hypermetropic eye is never in a state of rest while exercising the function of vision, as is the emmetropic eye when viewing distant objects.

In the myopic eye no distinct image can be had on the retina unless the object is brought nearer than infinity (which for optical purposes is represented by 20 feet). The parallel rays form circles of diffusion on the retina if distant vision is attempted.

In presbyopia, accommodation is rendered exceedingly and increasingly difficult by the crystalline lens losing its elasticity.

The excessive and continued strain upon the muscles of accommodation is a fertile source of exhaustion and irritation.

Hypermetropia and astigmatism, alone or combined, requiring the greatest strain, are more often the cause of reflex disturbance than is myopia.

A pair of normal eyes accommodated for a given distance will converge for the same distance and thus produce a single clear image.

If the eye be hyperopic, a greater nervous impulse and more active muscular contraction must occur in accommodation than in the normal eye.

For instance, if a hypermetropic eye is accommodated for one meter distance, it may require twice the energy necessary in a normal eye. Then if the effort at convergence is equal to that of accommodation, and the eye is focussed for one meter distance, the axes of the eyes will meet at a much nearer point; the eyes are not adjusted in their axes to the point for which they are focussed, and confusion results. It is to this great nervous perplexity more than to the muscular effort that the consequent exhaustion and irritation must be attributed.

The principle may be illustrated by a young person who attempts to use a pair of strongly magnifying glasses and finds, if continued for any length of time, the result to be vertigo, nausea and vomiting. That this result does not occur if only one eye be used, proves that the disturbance is due to the effort at perfect binocular vision.

A difficult and more complicated perplexity arises in cases of astigmatism, and still other nervous confusion is the result of myopia.

The symptoms arising from eye strain are many and varied.

The pain may be paroxysmal in character, or continual and subject to exacerbations, which are frequently brought about by worry, excitement, overwork, or any cause tending to lower the vitality. The most usual seat of pain is in the temples, supra-orbital and occipital regions, more rarely at the vertex. It may extend down the cervical region to the scapulæ. Gastric symptoms are frequent concomitants, and deceive the patient as to the origin of the suffering. There is present in a large proportion of cases a general nervous irritability, and even a fear of impending insanity. In all forms of ocular headach

there will be found asthenopia, nausea and vertigo in varying degrees. Where insufficiency of the internal recti muscles exists, sensory disturbances are frequent in the occiput, nucha, shoulders and back. Where insufficiency of the other recti is prominent, vertigo, diplopia and confusion are marked symptoms. In hyperopia and hyperopic astigmatism, the frontal headache is of most frequent occurrence. In myopia and mixed astigmatism, frontal, temporal and general headaches are about equally common. In cases combining hyperopia or myopia with presbyopia, frontal, temporal and occipital pain with vertigo are the phenomena observed. In pure myopia and presbyopia, nervous symptoms are seldom present.

The diagnosis of the etiological factor of headache is one of the most difficult problems a physician is called upon to solve. The number of different conditions upon which it may depend is legion.

Each case of headache (except, of course, those depending upon an evident febrile state) should be carefully and systematically studied. The habits, occupation, diet, and every detail as to mode of life should be ascertained. The family history should be inquired into, the urine carefully and repeatedly examined, and the state of the heart, blood, and especially of the eyes ascertained. In obscure cases, all possible sources of peripheral irritation should be considered, and malingering should not be forgotten. Some cases require the coöperative skill of several specialists (neurologist, gynæcologist and ophthalmologist) in order to investigate every clew in a thoroughly scientific manner.

The eyes should be examined as to the efficiency and balance of the muscles.

The test of refraction can only be accurately made, especially in a child, by the use of atropine to paralyze the accommodation.

A distinction must be made between a true ocular cephalalgia, in which the eyes are at fault, and the neuro-ocular cephalalgia, which is really due to an abnormal systemic condition (as neurasthenia, hysteria, or anæmia) in which the symptoms are called out by the use of the eyes.

The prognosis of headache dependent upon eye troubles is very favorable.

Stevens has treated 1,280 cases of chronic headache, and reports that permanent relief followed the correction of the ocular difficulties in 83 per cent. of the cases, improvement followed in 12 per cent., and failure in 4 per cent.

He also says of these cases that they were all typical cases of chronic headache, no cases of simple asthenopia or temporary headache being included.

He further remarks that in these cases no drugs were administered, so that nothing could be ascribed to the influence of medication, and that the results must be attributed solely to the removal of difficulties incident to the performance of the visual act.

It is to be observed also that the relief was not due to temporary stimulation of the nervous energy, as might result from electricity, drugs or a change of air or surroundings.

Norton reports a number of cases in which prompt improvement and relief of asthenopia and headache followed the correction of as low degrees of astigmatism as 25 D.

The essential element of the treatment is, of course, to remove the cause.

Correct refractive errors by proper lenses accurately adjusted.

The remedies for insufficiency of the recti muscles are:

1. Ocular gymnastics. This is accomplished by the use of prisms, and is soon followed by increased tone in the muscle treated.

2. Tenotomies and advancements of the muscles.

The use of eserine in cases of deficient accommodative energy is often of great temporary benefit. The instillation of atropine where the tension of accommodation is very great is often followed by immediate relief, and may, by removing a chronic condition of tension, give even permanent relief in some cases.

An important portion of the treatment is prophylaxis.

Children should have their eyes carefully examined before entering school. It seems a fitting subject for the State to consider the amount of suffering that might be saved and the increased capabilities that might be secured to its citizens as well as to those who are yet taxed without representation.

Outdoor exercise is of great benefit. Dr. Mittendorf says that many of his patients would be perfectly free from headache and able to lay aside their glasses could they

devote much time to outdoor muscular exercise, but if obliged to keep close in school, found glasses necessary.

He also refers to the fact that many people go through life hypermetropic and astigmatic without inconvenience, unless their health becomes impaired from some cause when asthenopia is manifested at once.

As a palliative measure a lotion composed of lavender, rosemary, camphor and alcohol is recommended as a local application to the closed lids and forehead.

The physician should never be persuaded to administer an opiate for a headache unless it be due to some incurable condition, as uræmia or organic cerebral disease. Hundreds of persons are rendered morphiomaniacs by the thoughtless administration of the drug for headaches.

AMPUTATION OF THIGH—FRACTURE OF HUMERUS—SARCOMA OF CHEST—TUBERCULAR LYMPH-NODES.

ROSWELL PARK, A.M., M.D.,* Buffalo, N.Y.

A week ago you saw an amputation of the thigh performed on this young woman to remove an enormous ulcerating malignant tumor. The dressing has not yet been changed, and I purpose doing so in your presence. After the patient was relieved of the constant poisoning from the horribly offensive mass, she improved rapidly, began to eat better and in every way justified the conclusion as to the necessity of operation. Her temperature has not reached 100° since the operation and has been practically normal since the second day thereafter. The stump was dressed without drainage and tourniquet was not removed till after the dressing was applied. You notice how little hemorrhage there has been. The outer layer of cotton is clean; only the iodoform gauze immediately over the skin has been moistened with blood. The healing is practically complete, although there is a narrow raw line where the flaps have not come entirely together. You will remember that the wound was sewed up rather loosely. The constant tremor of the stump is merely an indication of muscular weakness and is almost always observed. We will spray the stump with hydrogen peroxide solution and then smear it with sterilized petrolatum to prevent the dressings from sticking. The petrolatum is warm, having been recently sterilized. Iodoform is dusted over the stump and the dressing of iodoform gauze, bichloride gauze and cotton is applied.

If any vindication of modern surgical methods were necessary, this case affords it. Formerly, we used drainage in every case; now, acting on the belief that everything is sterilized at the time of the operation, we demonstrate our faith by making no provision for the escape of infectious material.

At the operation I told you that the woman gave no history as to the duration of the tumor. Since then she has told me that her foot was more or less sore for ten years; just how long a duration we may ascribe to the tumor, which was an osteosarcoma, it is impossible to say. The woman has suffered a sort of martyrdom to ignorance and poverty, though the lat-

*Professor of Surgery University of Buffalo.

ter need not have delayed the time of her relief.

When I was house surgeon we had to dress such a stump as this morning and night. The patients were subjected to more or less pain and discomfort by the frequent dressings. The carbolized oil which was used did not insure surgical cleanliness or even freedom from odor, and even the increased expense of dressings was a matter of importance. After three or four weeks we expected the patient to recover. If this woman had anybody to look after her at home she could leave the hospital to-day, leave the dressing on for a couple of weeks, then discard it, putting on, perhaps, a simple compressive bandage which the instrument makers like to have used for some time before fitting an artificial limb.

FRACTURE OF THE HUMERUS.

This man presents an acute condition of the left arm and an old one of the right shoulder. Let us investigate this latter first, as it will not subject the patient to so much discomfort. You will notice a flatness of the outer aspect of the shoulder, indicating an almost complete atrophy of the deltoid. The arm is moved freely and the patient says he can lift it away from the body, but you will note that he does not do so except by moving the scapula also.

The patient sustained a dislocation of the shoulder which was not touched for several days. Then he entered the hospital and Dr. Parmenter reduced the dislocation, but found that the head of the bone would not remain in place, indicating that there was an extensive laceration of the capsule. Accordingly, Dr. Parmenter cut in along the outer border of the arm and put the head of the bone into place, sewing the capsule around it. The atrophy of the deltoid could not be due to the operation, for although the scar indicates that the muscle was divided longitudinally, the circumflex nerve which supplies the deltoid could not have received any important injury from the division of a few of its minute branches. The nerve lesion and consequent atrophy of the muscle must have been due to the bruising of the circumflex nerve trunk by the inward displacement of the head of the humerus.

Yesterday the patient fell down cellar, about six feet and a half, and sustained a severe injury to the other arm. In this instance we lose a very valuable surgical guide, the comparison of the injured with the normal limb. For example, the left shoulder in contrast with the atrophied right shoulder appears enormously swollen. In reality it is only moderately so. The left forearm is freely movable, but not the arm. Thus the aids to diagnosis are somewhat restricted. The line of the axis of the humerus seems to point to the coracoid process, and this might suggest a subcoracoid dislocation. At the place where the head of the bone would be found in this dislocation there is a visible swelling, and when I press deeply over it, it yields hard tissue as bone would. Moreover, when I rotate the arm with my hand on the swelling, there is no moving body there. Indeed, with a dislocation, we should find preternatural immobility, whereas here I find preternatural mobility at a point below the deltoid. Pressure at this point causes pain, as it would not do if there were merely a dislocation. I can still feel a globular, hard body in the normal position of the head of the humerus. On pressing firmly over this body it remains motionless while I rotate the arm and I get a distinct crepitus at the line of preternatural mobility. We will now try Dugas' test, which depends upon the possibility of having the nearly straight line of the humerus tangent to the cenoidal thorax at more than one point. The hand of the injured arm is placed on the opposite shoulder. Now, if the head of the humerus be in its normal position away from the ribs, the elbow will touch the chest, whereas if the head is dislocated so as to lie nearly against the thorax, the elbow will stand out from the body. An attempt to execute this test causes so much pain that I will not persist in it, more especially as the movement has caused a marked bending at the point where crepitus was elicited.

After two or three days the ecchymosis, which is not now conspicuous, will be very apparent.

The forearm is held flexed against the chest, and a rubber adhesive strip is applied along the posterior and the anterior surfaces of the arm, leaving a long loop at the elbow. A narrow strip is wound spirally around the arm so as to hold the first in place. Over this a roller bandage

is applied and carried down in a few spiral turns below the elbow. We will attach a pulley to the side of his bed, and connect a weight with the loop so as to extend the arm. Probably from five to eight pounds will be necessary, enough, at any rate, to rectify the position of the limb in half a day by tiring the muscles into relaxation. After five or six days the patient will be able to get up, and, if the bone is then in good position, we will put on a Hamilton splint or bind the arm to the body, and let him walk around carrying a weight at the elbow.

SARCOMA OF THE CHEST.

The next patient is a man of forty with an enormous semi-solid tumor firmly attached to the thorax, which, he says, has been growing nearly seventeen years, and he has at length made up his mind to have it removed. His deliberation reminds one of the man who was confined in a little village jail for a number of years and then was struck with the happy thought to open the window and jump out.

From the patient's statement that the tumor originated in a small movable nodule, I believe that the growth was extrathoracic, but as it has gradually increased, it has became adherent to the bony structures and has doubtless involved the thoracic wall to some extent. I hope it has not also grown inwardly from the ribs, and in this hope I am encouraged by the circumscribed area affected. The tumor occupies the position of a left breast; it is hard and almost spherical, feeling like a croquet ball imbedded in the flesh.

On making the first incision, the knife plunges unexpectedly into a cystic pocket from which a quantity of dark, grumous material exudes. Perhaps you noticed that the ether caused a marked cyanosis. This has been relieved by the flow of venous blood from the wound. At the same time the signs of returning consciousness compel the administration of more ether.

I judge that the contents of the tumor are sarcomatous, broken down in places. A chisel will be necessary to separate the bone. In the lower part of the tumor the growth is osteo sarcomatous. The base of the tumor is so infiltrated with sarcomatous elements that it is impossible to effect a complete removal. The wound is closed with silkworm-gut sutures.

TUBERCULAR LYMPH-NODES.

This child presents an enormous enlargement of the cervical lymph-nodes and of the tonsils, which are of the same essential constitution. The latter are so swollen that it is difficult for him to swallow.

The mother also says that there are other enlargements apparent and that her physician has discovered like enlargements internally. In the left axilla I find the nodes enlarged, but not in the right. There is none discoverable in the groin. The mother's statement that there were enlarged lymphatics all over made me think of Hodgekin's disease or malignant lymphoma, which is a better term. In this disease the lymphatic enlargements are extensive, the spleen is enlarged, there is a decrease of red blood corpuscles and a relative but not actual increase of whites. Thus the diagnosis may depend largely on the microscopical examination of the blood. I am inclined to think, however, that the lesion is tubercular. If the case proves to be one of Hodgekin's disease I shall give Fowler's solution, increasing gradually to the point of tolerance, giving perhaps twenty-five drops a day, preferably in one dose hypodermatically. If the case is tubercular this treatment will be of value only as a general tonic. The removal of so many masses, even on the cadaver, would require two hours or more. In the living child such an operation is altogether too formidable. If the masses are tubercular we will give guaiacol internally and inject zinc chloride solutions into the nodes, hoping to get a bactericidal action or, at least, a condensing inflammation.

The case well illustrates the fallibility of snap diagnoses; that of malignant lymphoma would depend on entirely false premises, *i.e.*, the statements of the mother as to the widespread traces of disease.

Intra-Venous Saline Injections in Uremic Coma.

Dr. C. T. Parker (*Medical Record*) reports that at the Chambers Street Hospital, New York, this method of treatment is used in all subjects of uremic coma, and found to answer better than any other. If the patient is plethoric, it is supplemented by the taking of blood from the other arm. The injection is made into one of the veins at the bend of the elbow, one or two quarts of the saline being used.

COMMUNICATIONS.

FRACTURE OF THE LOWER END OF THE RADIUS.*

P. S. CONNER, M.D., CINCINNATI, OHIO.

As ordinarily met with, fracture of the lower end of the radius is the result of "cross-breaking strain" consequent upon over-exertion of the hand upon the forearm. Force received upon the palm, carried up through the os magnum and the projecting line of junction of the scaphoid and semi-lunar, if sufficient to break the radius must do so in a more or less longitudinal direction, not transversely. Overbending of the forearm bones may, and at times does, cause fracture of the radius which is approximately transverse; but the level of the break is always higher than that of the common "wrist fractures."

Experimentally, by over-extension, every variety of the fracture under consideration can be produced, from the simple crack through the articulating extremity to a separation and displacement of the carpal fragment equal to that of the most severe injury coming under professional care. Whatever its degree, displacement is due to the secondary action of the anterior radio-carpal ligament upon the fragment already dragged off from the radius; and it is in the majority of cases largely maintained by the binding force of an untorn dorsal strip of periosteum, as originally shown by Pilcher. Much has been written, and more said, respecting impaction of the dorsal compact edge of the lower end of the upper fragment in the cancellous upper surface of the lower fragment; and proof of its existence has been found in inability to properly adjust the fragments by traction upon the hand in the direction of the long axis of the forearm. But, unless it may be under very unusual conditions, a force sufficient to pin the upper fragment in the lower would be sufficient to and would split the lower fragment into two or more pieces and consequently prevent impaction. The resistance to replacement by direct extension is, in the great majority of cases, probably in all, not in any fixation of the upper in the lower fragment, but in the untorn periosteal band already mentioned, Only when such band is absent because of complete laceration at the time of injury, or it has been torn by the dragging force exerted through the hand, can proper apposition be secured by such manipulation. But if instead of pulling upon the hand it be over-extended, brought, in other words, in the position in which the fracture occurred, any existing periosteal band is at once relaxed; and the moderate pressure upon the upper end of the lower fragment is sufficient to carry this fragment into its proper place, at times with a very audible snap. Little or no pain is produced; no anesthetic is required; the securing of proper apposition of the fragments is the work of but a few seconds. Personally I have never had any difficulty in thus adjusting a case coming under care within twenty-four hours after receipt of the injury. If there is, as there certainly is at times, a fixation of the ulnar styloid process under or in the posterior annular ligament, such process will be set free either by simple over-extension or by such combined with rotation. Once properly apposed, there is practically nothing other than outside violence to produce a secondary displacement. The weight of the dropped hand strongly tends to maintain apposition, and additional security is afforded through the action of the tendons crossing over the line of break on the palmar and dorsal surface. The supinator longus through its styloid attachment does without doubt act upon the lower fragment, but such action is too feeble to cause displacement.

Proper adjustment (and the earlier it is effected the better) will prevent or greatly limit effusions, exudations and adhesions. The unfortunate result, at times observed, which has been attributed generally to age, to rheumatic or gouty habit, to too short or too long employment of splints, to improper conduct on the part of the patient or carelessness on the part of the doctor, is commonly, very possibly always, due to

* Trans. Surgical Section Amer. Med. Ass'n, 1894.

imperfect adjustment at the time of the original dressing; the displaced lower end of the upper fragment making such pressure upon the soft parts upon the palmar surface near the wrist as to interfere with both arterial and venous circulation, especially the latter, and that not only directly but indirectly through the induced nervous disturbance. Under such circumstances the ordinary treatment by splint and bandage only makes a bad matter worse, the vessels and nerves being compressed between bone and board. That which is absolutely essential to thoroughly satisfactory repair is early and complete adjustment. This is one of the few fractures in which the chief difficulty lies in securing, not maintaining, apposition. Once secured, only the simplest after-treatment is really required, a band around the wrist perhaps, to lessen the after-spreading due to separation of and later somewhat misplaced attachment of the inter-articular cartilage.

In view of possible after-ligation, as professional opinion is now, it is wiser as a rule to employ some form of splint, plaster-of-paris or other, never extending below the wrist line and thus supporting the hand, which should be allowed to hang free. But the use of such splint is not necessary so far as the break is concerned, provided (and this proviso must be kept constantly in mind) complete apposition of the fragments is secured.

Its manner of production well understood, the difficulties in the way of primary adjustment duly recognized, and the first dressing properly made, this fracture becomes one of the simplest to treat, causes little inconvenience, comparatively, to the subject of it, and is very satisfactory in its end-result.

TRANSLATIONS.

THE FACTORS OF ANEMIA IN DISEASES OF THE RESPIRATORY PASSAGES.

Chabory (*Le Progrès Médicale*, June 16, 1894) remarks that the respiratory apparatus, the organs of the absorption of oxygen, supplies an indispensable unit in the complete evolutions of the red corpuscle. Thus there may be noticed in most of the diseases of the respiratory tract an anemia, the principal factors of which are the following:

Diminution in the caliber of the air-passages. M. G. Sée noticed in 1888 a pseudo-anemia from respiratory inanition. M. Balme has remarked the pallor of children who have a hypertrophy of the palatine tonsils; in young girls the menses appear late, are scanty, and are easily suppressed for long intervals. He adds that not only are the children pale and debilitated, but they are subject to an extreme prostration; the free entrance of air into the chest being prevented, the thorax cannot dilate itself as it should, and the normal and necessary ration of air is not received.

Diminution in the air-absorbing surface and interference in the capillary circulation. If the air-absorbing surface is restricted the quantity of oxygen passing into the blood is diminished, and the circulation of blood in the capillaries is retarded. The lesions of the lungs which hinder hematosis are bronchitis, due to infiltration and thickening of the bronchial mucosa, obstruction of the bronchi, and the covering of their inner wall with muco-pus; asthma, in which there are vasomotor troubles with crises of expiratory spasm; whooping-cough, with the lesions of bronchitis; in congestion, in which there is a flattening of the alveoli by the engorged capillaries; in edema, with serous infiltration of the alveolar walls; in apoplexy, from thrombosis or embolism, in which there is a suppression of a part of the respiratory filter which diminishes hematosis. In emphysema there is a sclerosis of the inter-alveolar walls, absence of contractility of these walls, and consequently a retention of air in the alveoli; in pulmonary sclerosis there is also

a thickening of the inter-alveolar walls; in cancer and tumors of the lung and pleura, there is an invasion of the pulmonary parenchyma by the tissue of the neoplasm; in pleurisy, pneumo-thorax, hydatid cysts, there is compression of the lung, flattening of the alveoli and atelectasis, which diminishes the gaseous exchange. The lungs of broncho-pneumonics present the lesions of bronchitis, of capillary bronchitis; in these patients a whole lobe or a whole lung is hepatized, not permitting the entrance of air to the blood. Acute granular phthisis, characterized anatomically by a multiplicity of miliary granulations, which produce a perinodular hyperemia, a congestion and splenization.

Febrile affections of the respiratory passages. All febrile diseases are accompanied or followed by an anemia, more or less durable and grave, the degree of which is proportionate to the intensity and duration of the fever.

Benign and malignant neoplasms of the respiratory passages. These tumors diminish the caliber of the air-passages, the seat of hematosis, and thus resulting in anemia. Moreover, there is an anemia symptomatic of cancer, whatever may be its seat and its complications, resulting from a diminution in the number of red corpuscles, an increase in the number of white corpuscles, pronounced corpuscular deformity and a decrease in the weight of the solid constituents of the blood.

Hemorrhages of the respiratory passages. These are a cause of anemia, the gravity and duration of which depend upon the amount of blood lost and the frequency of the hemorrhages. The anemia consecutive to these hemorrhages is a true insufficiency in the blood-mass and has been termed oligemia or spanemia.

Pathologic secretions of the respiratory mucosa. The extended surface of the respiratory mucosa becomes covered in certain diseased states with a very abundant secretion, and this secretion is in part a nidus of infection and also a source of spoliation and loss for the entire organism. All suppurations are accompanied or followed by anemia. The more extended the suppurating surface and the more abundant the suppuration the graver the anemia.

Troubles in other organs provoked by affections of the respiratory passages and the causes of anemia. Chronic diseases of the lungs, among others, emphysema with or without catarrh, asthma, chronic pulmonary phthisis, cause dilatation of the right heart, its fatty degeneration, disorders of the circulation, and consecutive modifications in the composition of the blood. Digestive troubles complicating nasal, bronchial and pulmonary affections are very common and very lasting, and these undoubtedly react upon the composition of the blood. Nervous phenomena, such as cough, cephalalgia, insomnia, depression, hypochondriasis, which accompany a number of respiratory affections are equally factors of anemia, as are also long confinement to bed and the rest necessitated by the great weakness of the patient or the dread of hemoptysis.

Composition of the blood in diseases of the lung. In bronchitis the hemoglobin does not fall below 100 grams. In acute pneumonia Quinquaud has noticed that destruction of hemoglobin occurs in the course of the febrile stage; moreover, during the febrile period the serum becomes impoverished in solid materials. In pulmonary emphysema there is also a diminution in the amount of hemoglobin.

To conclude, the author finds that the factors in the anemia in diseases of the respiratory tract are: 1. Diminution in the caliber of the air-passages. 2. Diminution in the air-absorbing surface and interference with the capillary circulation. 3. Fever. 4. Neoplastic evolutions (cancerous) of the respiratory tree. 5. Hemorrhages of the respiratory tract. 6. Pathologic secretions of the respiratory mucosa. 7. Diseases provoked in other organs by affections of the nose, bronchi and lungs.

D.

Cerebral Edema.

Dr. George J. Preston draws the following conclusions in his paper on cerebral edema, in the *Journal of Nervous and Mental Diseases:*

1. Cerebral anemia should receive recognition, both from the clinical and pathological standpoint.

2. Edema of the brain follows the law of edema elsewhere in the body, with the important exception that these laws must of necessity be considerably modified by the anatomical arrangement of the lymph spaces of the brain and its membranes.

3. The effused serum may exert injurious mechanical pressure, and also offers occasion for toxic influences.

CORRESPONDENCE.

STATUS THYMICUS—GONOCOCCI IN GONORRHŒA—TREATMENT OF MALARIA WITH METHYLEN BLUE—EXPERIMENTS WITH TOLYPYRIN AND TOLYSAL.

VIENNA CORRESPONDENT TO THE MEDICAL AND SURGICAL REPORTER.

STATUS THYMICUS.

Dr. T. Schnitzler, Assistant to Professor Albert in the General Hospital, reported on this interesting subject before a recent meeting of the Imperial Royal Society of Physicians of this city. The case was that of a woman, 31 years old, who was suffering from a severe case of Grave's disease. As strumectomy in Grave's disease was performed with good success by several surgeons during the last years, Dr. Schnitzler also decided on that operation. He performed the extracapsulary extirpation of the whole of the right part of the goitre as well as the middle lobe, which was greatly developed, and almost two-thirds of the left lobe. After operation and the application of the dressings the patient's respiration was quite normal, and she also showed reaction to irritation. A quarter of an hour later the respiration suddenly assumed another character; it became flat, and some minutes later the respiration as well as the pulse were quite abolished, and the pupils became maximally dilated. Attempts at revival were in vain and the patient succumbed.

The post-mortem examination revealed the presence of that condition of the body which Prof. Arnold Paltauf has called "status thymicus." They found a considerable persistency of the thymus; and all the lymphoid formations, such as the lymphatic glands, the tonsils, the follicles of the intestines and those of the base of the tongue as well as those of the spleen, were considerably enlarged. There was, moreover, a considerable narrowness of the aortic system; the heart was found to be dilated; red-colored marrow was detected in the large parts of the tubular bones; the brain and the lungs were in a state of anæmia.

From the works of other authors, and particularly those of Professor Arnold Paltauf, it resulted that the condition of the body referred to above—the so-called "status thymicus"—was characteristic of a particularly impaired resistence of such individuals. Professor A. Paltauf has also shown that the opinion according to which death in such cases was due to suffocation by pressure of the enlarged thymicus, was not correct. In cases of the so-called "deaths in narcosis," the "status thymicus" also played a most important part; this was proved by the researches of Professor Richard Paltauf in the Vienna Anatomo-Pathological Institution, and also by the fact that in two cases of "death in narcosis" which had occurred during the last year at Professor Albert's clinic, the post-mortem examination held revealed the presence of the "status thymicus."

The case reported by Dr. Schnitzler was, within a proportionately short interval of time, the third case in which a patient operated on for Grave's disease died as the direct result of the surgical interference, and where the post-mortem examination could prove the persisting condition of the thymic gland. Bardeleben and Gluck also reported, each, on a similar case. Gluck seems to attribute the death in such cases to suffocation owing to pressure of the enlarged gland, whereas Dr. Schnitzler pointed out that the fatal issue in such cases, including those of Bardeleben and Gluck, was to be explained in the way referred to above—that is to say, as the result of an impaired resistance of the organism.

ON THE EVIDENCE OF GONOCOCCI IN GONORRHŒA.

Docens Dr. Finger made a valuable contribution on this subject to the same society. "Wertheim," he said, "was the first to cultivate gonococci on human

blood-serum by means of plate-cultures." This method was, however, too complicated, and Dr. Finger found the cultivation of gonococci on "urine-agar" to be the best one.

As to the biology of the gonococcus, it must be remarked that an acid soil of culture suited it better than a weak alkaline one. The gonococcus began to develop at a temperature of more than 25° C., and a temperature of 36° C. proved very favorable, whereas that of 40° C. killed it. The gonococcus was sensitive to drying processes.

The vitality of the gonococcus in gonorrhœal pus was of great importance from a practical and medico-legal point of view. Cases of transmission of gonorrhœa by means of polluted shirts had been recorded by several authors; this, however, Dr. Finger pointed out, was only possible so long as the pus was not dried up. Gonorhœal pus, so long as it was not dried up, gave positive results, and frequently these results were obtained after thirty-six hours. When the pus was dried up, he could no longer succeed in obtaining cultures, even after moistening with sterile water.

The gonococcus was little sensible to chemical agents. The action on it of nitrate of silver (1:1000) and sublimate (1:6000), during two minutes, could not kill it. Cultures thus treated still gave positive results on inoculation.

As to the question concerning the immunity of urethritis against new infection, the lecturer remarked that in three cases of cured acute urethritis and two cases of chronic urethritis, the inoculations with gonococci gave positive results which could also be confirmed by microscopical examination. These inoculations proved, at the same time, that the gonococcus really was the pathogenic agent in gonorrhœal processes.

Dr. Finger then discussed the question of the relation of the gonococci to the inflammatory foci. In many cases he succeeded in producing the symptoms of acute inflammation of the joints by means of inoculation. In these cases, as well as in those of circumscribed peritonitis, the presence of gonococci could no longer be proved after twenty-four hours. In the cases of eight patients, with imminent fatal issue, the inoculation gave, on three occasions, a positive result, whereas in the five other cases the result was negative. In the first mentioned cases there was no fever, or only a slight one, whereas in the other instances there was considerable elevation of temperature. It was a well-known clinical fact that febrile temperatures had an influence on the course of urethritis, viz., it made the secretion stop, which afterward appeared again. The high febrile temperature thus seemed to confer a temporary immunity against the gonococci, and the immunity of mammals also seemed to be explicable by their having higher temperatures than man.

As to the relation of the gonococcus to the tissues, the lecturer pointed out that Neisser, of Breslau, had opposed his opinion that the gonococci quickly penetrated into the connective tissue. This was, however, found to be the fact in many anatomical examinations of such cases. Frisch had met with gonococci in the glands and the connective tissue of a case of gonorrhœa of the rectum. He even detected them in the surrounding muscles.

With regard to the complications of gonorrhœal infection, he said that they had formerly been looked upon as the product of a mixed infection until Dr. Wertheim had shown that these complications were solely due to the gonococcus. Gonorrhœal arthritis was the most frequent complication, and was, in most cases, to be met with in the primary forms of gonorrhœa. In the case of a boy eight days old, who was suffering from ophthalmoblenorrhœa with gonitis, numerous gonococci were found on puncture of the joint.

Respecting the coloring of the gonococci, the lecturer said that the coloring with borax-methylenblue was the simplest method. The microscopical sections were placed in a mixture of 5 parts of borax and 5 parts of methylenblue in 100 parts of water; then they were washed and discolored in a one-half per cent. solution of acetic acid, and finally kept for a short time in alcohol, Bergamot oil and Canada balsam. These specimens were very sensible to the decoloring influence of alcohol, but less so to acids. The specimens under consideration had, however, the disadvantage that they lost their color after from three to four months.

Dr. Finger arrived at the following conclusions:

1. The gonorrhœal rheumatism is a

true gonorrhœal affection caused by gonococci.

2. The gonococci are also found inclosed in pus cellules in inflammatory processes.

3. The gonococci are able to produce true suppuration of the connective tissue.

4. The view that the gonococcus has an exceptional position, inasmuch as it only produces superficial catarrh of the mucous membranes, must be entirely given up, and the gonococcus is quite analogous to the staphylococcus, the streptococcus and the micrococcus pneumoniæ.

THE TREATMENT OF MALARIA WITH METHYLENBLUE.

Dr. W. Dombrowski reports, in a recent number of the Polish medical journal *Gazeta Cźarska* upon his experience in the treatment of malaria with methylenblue. He had treated five cases of malaria by means of this drug. In the first case 5 grammes of methylenblue were administered within ten days; the drug was well supported. The plasmodia disappeared, the temperature decreased and the spleen diminished in size. In the second case under consideration, the plasmodia also disappeared, and the attacks of the disease were stopped. In the third case, 2.5 grammes was the total amount given; no plasmodia could be detected any longer, and no attack was presented during tho. last three days of the patient's sojourn in the hospital. In the rest of the cases the success was a similar one.

The treatment with methylenblue was commenced at different stages of the disease, and it was indifferent for the therapeutical success as to whether the drug was administered before, during or after the attack. One attack, however, invariably occurred after the administration of methylenblue, but this attack was generally less severe than the foregoing ones, *i.e.*, without rigors and perspiration, and only characterized by slight elevation of temperature. It was only in two light cases that the methylenblue immediately stopped the attacks. In other cases the drug had to be given for at least forty-eight hours in order to remove the attacks.

Out of eleven respective cases which Dr. Dombrowski had an opportunity of observing, ten were entirely cured. In the eleventh case under consideration, the fever, indeed, disappeared, but plasmodia could be proven to be present in the blood after seven days from the last attack, and the spleen was still rather enlarged.

Dr. Dombrowski concludes, from the uniform good results which he had obtained in the cases now referred to, that methylenblue may be considered to be a specific remedy for malaria. The most essential property of this drug consists in killing the plasmodia. As to the bad after-effects, Dr. Dombrowski saw nausea and vomiting only in one case in which methylenblue was administered for a long time; otherwise the remedy was well supported. No albumen could be proven in the urine; the latter was merely of a blue color after the first dose of methylenblue.

EXPERIMENTS WITH TOLYPYRIN AND TOLYSAL.

Dr. Aladár Anjeszky, of Budapest, has carried out a number of experiments with tolypyrin and tolysal. As to the antipyretic effect of tolypyrin, it was observed that in the case of individuals who were free from fever, from 3 to 4 grammes of the drug—one gramme being taken every two hours—diminished the temperature only from 0.5° to 0.8° C., whereas in febrile patients the effect was very strong and prompt. The patients, according to the degree and the quality of the fever, received from 1 to 4 grammes of the remedy in doses of 1 gramme every hour. After the administration of the first powder the temperature was measured half an hour later, and later on every hour. In the case of moderate fever the temperature decreased after the administration of the first gramme of the drug, and after half an hour it diminished only some tenths of a degree. The decrease after three hours reached from 1° to 5° C. Some perspiration was in most cases observed at the beginning of the effect of the remedy. In slight fever one could obtain a state of apyrexy lasting from 7 to 8 hours with from 1 to 2 grammes, and when the temperature rose anew it was no longer accompanied with rigor. In high fever, from 3 to 4 grammes were required to produce apyrexy, but it then lasted for from 10 to 16 hours. Even in the stage of the acme 3 grammes of tolypyrin were able to lower the temperature from 40° C. to 36.8° C., and the patient remained free from fever during 14 hours. In one case of bilateral

infiltration of the apices of the lungs the drug caused a subnormal temperature of 34.8° C.

Among the concomitant effects produced by tolypyrin, the perspiration must be noted at first. The sweating was not very severe; only in the case of phthisis it used to be specially copious. Its duration varied, but generally it did not overlast the apyretic stage. Of gastric symptoms, nausea and vomiting were noted on two occasions; in one instance, urticaria was seen. In general, the drug was well supported by the patients. The tolypyrin failed to prove useful as an anti-rheumatic and analgesic.

With tolysal, *i.e.*, the salicylate of tolypyrin, the following results were obtained:

In individuals free from fever, the tolysal, when from 5 to 6 grammes of it were administered in hourly doses of 1 gramme, lowered the temperature only nine-tenths of a degree. In the case of patients with moderate fever, the temperature was not influenced by 1 gramme of tolysal. In order to produce an antipyretic effect, from 2 to 3 grammes of tolysal had to be administered in doses of 1 gramme every hour, whereas it had no effect when it was given every two hours. The decrease of the fever only occurred after the administration of the second dose (1 gramme), after from one-half to one hour, but this decrease did not amount to more than some tenths. A more intense effect was obtained after the third powder, but the decrease in this case did not exceed 1° C. From 4 to 5 grammes of tolysal, administered in doses of 1 gramme at intervals of one hour, were followed by a decrease of temperature of from 1½° to 2° C. In high fever, from 6 to 8 grammes had to be given to obtain an effect on the temperature; thus in a case of abdominal typhoid fever, 5 grammes of tolysal lowered the temperature only 1° C., whereas tolypyrin proved excellent in the same case.

Excellent results were obtained with tolysal in the case of rheumatism of the joints. In these cases the patients received 6 grammes of tolysal daily, and the effect was already on the second day a striking one; the pains diminished, the inflammatory symptoms of the parts and the fever disappeared, and the general condition improved.

Dr. Anjeszky arrives at the following conclusions:

1. Tolypyrin is a reliable antipyretic remedy.
2. Small doses of tolypyrin (1 to 2 grammes) cause an apyrexy of from 7 to 8 hours, and larger doses (3 to 4 grammes) one of from 10 to 16 hours.
3. Tolypyrin has no bad after-effects.
4. Tolypyrin has not proved useful as an analgesic.
5. Tolysal is but a weak antipyretic, and it exerts an influence only in large doses.
6. The antipyretic effect of tolysal does not extend over more than 4 hours.
7. Tolysal is an energetic anti-rheumatic, and may be substituted for salicylate of sodium where this cannot be borne.
8. In the case of pains of a rheumatic origin, tolysal exerts an analgesic influence.

Dietetic Treatment of Patients Threatened with Cerebral Hemorrhage.

Dr. Joseph Collins, in *Food:* The diet for these patients, varying as it must with individuals and their digestive peculiarities, should be mainly of carbohydrates, sparingly of hydrocarbons, and still more sparingly of nitrogenous food stuffs. The essential points to remember about the latter two are, that the first is given as an energy producer and as an aid in the complete oxidation of other food stuffs, and that when the last one is administered it should be seen that its complete oxidation is thoroughly performed. So much for the administration of the organic food stuffs. A word concerning the inorganic. Water, particularly, is necessary. The important part played by water in the treatment of arterial degenerations, particularly when such degenerations are dependent upon improper and insufficient metabolism, is not easily overestimated. The presence of it in the digestive tract, influencing as it does the rapidity of osmosis, filtration, and the other principles involved in absorption, and its effect in lowering the specific gravity of the blood after it is absorbed, are both very important, not to speak of its being the vehicle for the removal of most of the effete matters from the system. It favors absorption, facilitates oxidation, and promotes thorough metabolism. In all cases of arterial degeneration, with threatened cerebral apoplexy, water should be given in small quantities, frequently repeated, and should thus become a staple part of the diet.—*New York Med. Times.*

THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, OCTOBER 27, 1894.

EDITORIAL.

THE ETIOLOGY AND PREVENTION OF DIPHTHERIA.

At the Eighth International Congress of Hygiene and Dermography, at Buda-Pesth, there was a most interesting and instructive discussion on diphtheria, more especially on its etiology and prevention. The following summary of the conclusions by Loeffler is of much importance:

1. The productive agent of diphtheria is the diphtheria bacillus. Dispute as to the etiological definition of this bacillus exists no longer. We can, therefore, henceforth indicate as diphtheria such forms of disease as are infested with the bacillus.

2. Not infrequently cases appear in the early stages to the clinical observer as true diphtheria, which, however, are caused by other organisms, as streptococci, staphylococci, etc., and in light or graver form may be mistaken for true diphtheria. But the differential diagnosis can be made through bacteriological research. . . .

3. Diphtheria epidemics show a various character, as do many other epidemics of infectious disease. . . . In the same epidemic instances of severe and light forms of the disease frequently alternate irregularly.

4. The variations, of course, will be determined by several factors: (*a*) By difference in the number and virulence of the diphtheria bacilli; the causes of the latter are not yet absolutely known. (*b*) By concomitant bacteria, and, indeed, as much by pathogenic as saprophytic; the processes of infection with regard to the diseased mucous membrane in the passages and in the nose, appear to influence the course of the disease unfavorably, in part by increasing the virulence of the bacilli, in part by weakening the body through absorption of decomposed products. (*c*) By individual tendencies not yet thoroughly recognized.

5. The diphtheria bacillus can appear in the passages, especially of the nose, of separate individuals without causing indications of sickness, which it first induces when it has actually established itself. Lesions of the mucous membranes, small eruptions, catarrhal changes are favorable to its residence. In brief, meteorological conditions, giving admission by the first approach to catarrh, especially cold, damp weather, appear to favor the sickening from this cause. But this influence has to be more closely observed.

6. Diphtheria is most rapidly communicated by direct contact between sick and well, through spitting, coughing, sneezing, kissing and grasping of the hands, whereby the hands come into contact with fresh secretions, but also freely through utensils which the sufferer has fouled with his excretions, by beverages, food, eating and drinking vessels, cast-off clothes and other articles as pocket-handkerchiefs, playthings, even long after their actual infection.

7. The sick one is infectious so long as he has bacilli upon the mucous membranes. The bacilli usually disappear with or very soon after the disappearance of the local signs, but they may be detected still lively and virulent in the passages or nose for weeks or even months.

8. In organic matters condensed and excluded from light the bacilli can maintain themselves for a period of months outside the body. Accumulations of dirt, dark and closed dwellings favor thus the preservation of bacilli and the extension of disease.

9. As a specially noticeable vehicle for the extension of the disease is to be noted the crowding together of susceptible individuals, especially in families of many children. . . . Other gatherings may offer facility for the extension of the disease, such as schools, barracks and the like.

10. The diphtheria bacillus is so far not identified with certainty as the cause of other diseases similar to diphtheria, or of other spontaneous disease of lower animals. The possibility of the conveyance of true diphtheria from sick animals to human beings is thus outside of our present knowledge. . . .

11. The prophylactic means to be considered are: (*a*) Care for cleansing, keeping dry, sufficient ventilation and lighting of the dwelling; (*b*) Careful cleansing of the mouth and nose, gargling with weak solutions of common salt and carbonate of soda, thorough brushing of the teeth, extraction of bad teeth, attention to the deeper cavities of the tonsils and the removal of hypertrophied tonsils; (*c*) Cold douching of the throat in times of diphtheria prevalence.

12. Every case suspected as diphtheria must, when possible, be bacteriologically investigated. The physicians should have easy access to the materials for carrying on the culture work. The investigation should be carried on by a specialist, as in cases of cholera.

13. All cases proven bacteriologically to be true diphtheria, as well as all cases suspected as diphtheria, . . . should be dealt with under police regulations. [Strict isolation from other individuals and the most rigid disinfection carried out.]

14. In order to restrict as much as possible the spread of the bacilli by the sick, a local anti-bacillar treatment must be employed with a view to prophylaxis against the early stages of the disease.

15. One of the most effective means against the spread of diphtheria to be cared for, is the protective inoculation of susceptible individuals in the neighborhood of the patient, especially children. In proportion as the innocuousness of Behring's serum cure through preventive injection is established for curing or prophylaxis, it appears worth while to develop further, as far as possible, the art of inoculating it in families and in school classes in which diphtheria cases have occurred.

16. In every case of diphtheria disinfection is imperative. This is needed for all utensils for the sick. . . .

17. Convalescents from diphtheria must not mix freely with others (or children go to school) until bacteriological investigation has proved the removal of the bacilli, and the sick, after a warm bath with soap, have been thoroughly cleansed and have put on clean clothing.

18. On the outbreak of diphtherial epidemics notification should be given in the public press.

ABSTRACTS.

THE NOSE AS A FREQUENTLY UNRECOGNIZED CAUSE OF DISEASE.*

LOUIS J. LAUTENBACH, †M.D., PHILADELPHIA, PA.

Hitherto the nose has been rather a neglected organ. It has only been of recent years that we have begun to learn of the influence it exerts upon even remote parts of the body. That this neglect has occasioned a great deal of suffering which could have been prevented, is evident to all who have devoted themselves to nasal medicine. Unfortunately, nasal troubles being rarely accompanied by pain, are in consequence too often neglected by the physician as well as the patient, and a difficulty which might have been easily curable at first occasions a condition which may remain through life and even terminate in death. Naturally, those organs are affected which are either anatomically or functionally connected with the nose. It is connected anatomically with the organs of sight and hearing, with the throat and lungs as well as the cerebrum; indeed, the olfactory nerve is but a bulbous elongation of cerebral tissue containing gray matter.

Functionally, it is to be considered not only as a sense organ, but as having imposed upon it other duties. It drains the tears from the eyes, and through the Eustachian tube the mucous secretions from the ears; it aids in the function of hearing by allowing the sound to pass freely up the Eustachian tube; it prepares the air for the lungs by moistening and heating it and cleansing it from particles of dust; and in some way as yet unknown to us, exercises some control over the faculty of memory.

Considering the intimate relation existing between the nose and these other parts, it is easy to understand how widespread, and how subtle and yet serious may be the mischief occasioned by neglected disease of this organ.

Perhaps nowhere is its influence more often discernible than upon the air passages. Pharyngitis, tonsillitis, laryngitis, bronchitis, and even asthma, pneumonia and pleurisy are traceable directly to a want of the proper performance of the nasal functions as well as to a direct extension of the nasal inflammation. Pharyngitis and tonsillitis are often occasioned or aggravated by the irritation of the nasal discharges flowing constantly over the posterior wall of the pharynx. Simple catarrhal laryngitis and bronchitis are rarely found except in connection with head colds, and they are very difficult to cure, unless the nasal conditions be relieved; in fact unless these are relieved, the bronchial and laryngeal inflammations are prone to recurrence. How often do we hear of children who are, as we say, subject to bronchitis! Unless this tendency is checked, the child is apt to be stunted in his full growth, and in addition will probably show some chest weakness throughout life. Fully nineteen out of twenty such cases can be cured only by careful, systematic treatment of the nose in connection with the chest trouble. Pneumonia and pleurisy, when occasioned by nose disease, usually originate through mouth-breathing, preventing the proper preparation of the inspired air. This is more frequently the cause of these diseases than it is usually considered to be. That this want of proper preparation is very dangerous, is shown by the fact that the operation of tracheotomy is almost invariably followed by a pneumonia. It is true that by this operation the air is carried more directly to the chest than by mouth-breathing, but mouth-breathing exerts precisely the same influence as the tracheotomy tube, except only in a more limited degree. In mouth-breathing the surface over which the air passes, before it enters the lungs, is diminished to perhaps a little over half the normal, whereas after the operation of tracheotomy, it is diminished to less than one-third normal.

*From advance proof-sheets Codex Medicus Philadelphiæ, No. 1.

†Surgeon to the Pennsylvania Eye and Ear Infirmary; Throat and Nose Physician to Odd Fellows' Home, etc., late Chief of Eye and Ear Clinic, German Hospital.

What proportion of cases of asthma are caused directly and indirectly by nose disease, I have no means of knowing. That, however, it is not an infrequent cause, has been taught me by experience. Quite a large number of cases of asthma present markedly abnormal conditions, particularly bony and mucous hypertrophies, occasionally combined with polypi. I have been fortunate, in all the cases which I have treated, in at least relieving the asthmatic condition and, in a large proportion, curing it by careful nose treatment.

Perhaps next in frequency to the diseases of the air passages thus occasioned are the stomachic and often the consequent intestinal disorders; children, particularly infants, are especially the sufferers. The nose colds are accompanied by profuse discharges which are not gotten rid of by the mouth, as is usually the case with adults, but are swallowed and, fermenting in the stomach, give rise to cramp-like pains, vomiting and intestinal disorders, the food not being digested in consequence of the irritation of the stomach and intestinal walls by the products of fermentation. In this way arise many of the cases of inanition, cholera infantum, etc. In the adult, either through neglect or more often through the passing of the mucous discharge down the œsophagus during sleep, we are apt to have flatulent dyspepsia and an acid stomach; when the cause is unrecognized, these cases progress for years, until the disease is well-nigh incurable, on account of the changes which have occurred in the walls of the stomach, through the constant irritation by the ferments produced.

All practitioners well know that most diseases of the ears proceed either from an extension of nasal catarrh, or result from the closure of the nose which prevents the proper ventilation of the ear and the flow of mucus through the Eustachian tube. In this way, a closure of the tube is produced which results in an inflammation of the middle ear, often with involvement and perforation of the drum head, and even extension of the inflammation to the mastoid cells. These conditions are more prone to occur in the infant than in the adult, as the Eustachian tube, being so much smaller, is more easily occluded, and again, the bony walls being much thinner and more porous favor the ready extension of septic influences.

Upon the eye the nose exerts its influence by an extension of the inflammation up the ductus ad nasum, as well as by occlusion of the same. Thus are caused lachrymal abscesses and epiphora, catarrhal conjunctivitis as well as corneal troubles. Some authorities consider that phlyctenular conjunctivitis may be thus occasioned. I have frequently relieved severe persistent pain of the eyeball, as well as cases of asthenopia, by nose treatment, after the most careful eye treatment had failed.

Eczemas of the face, observed in patients suffering with nasal catarrh, especially as found in children, are rarely curable unless the nose be restored to its normal condition.

As illustrating cerebral symptoms occasioned by nose disease, I will mention severe, persistent headaches, giddiness, loss of memory and of ambition, and a generally demoralized condition of the mental faculties; all of these, in many instances, have been relieved by nose treatment. Perhaps the most marked and noticeable of these symptoms is the loss of memory, as it is now a well established fact that nasal troubles often profoundly influence this faculty. Perhaps there is no class of patients who are more grateful when relieved than those who are thus affected. The failure of memory, seeming to threaten the very foundations of the soul, brings close to the patient the possibility of that faculty being lost which enables him to be in close communion with his fellow-man—rationalism (or sanity). I am at present treating a most marked case of this kind. She feels as if she were already half insane; fortunately, decided improvement has occurred as a result of the treatment of the nose.

Even in epilepsy it is sometimes the determining factor. I know of two cases in whom the spasms disappeared, after careful nose treatment.

Hay fever, the exact pathology of which is as yet somewhat in doubt, which exhibits phenomena attributable to the nervous system, as well as such as originate in the air passages, has, in numerous instances, been cured by the removal of hypertrophies and polypi from the nostrils, and the contraction of the soft, congested, elastic nasal tissues.

In cases of general ill health of a mild type, presenting often some irritability of the throat, some slight stomachic disorder,

particularly flatulency with a tendency to constipation, with a sodden colorless skin inclined to be cold, with an inaptitude for exertion, especially mental effort, it will occasionally be found that these symptoms arise from partial nasal occlusion, with night mouth-breathing and consequent deficient oxygenation of the blood.

I trust even these few cursory remarks will prove the importance of the more frequent examination of the nose and its subsequent judicious treatment.

In all diseases of the ears should this examination be made. It will prove valuable in many cases of disease of the upper air passages as well as of the chest; particularly will its value be appreciated in studying these diseases in children. In cases of stomachic and intestinal disorders, the procedure should not be neglected. With children it should invariably be made. It is essential in many cases of diseases of the eyes. I believe it should not be omitted in obscure cerebral diseases, particularly if there be loss of memory. In obscure cases of ill health without any marked lesion, this examination should be made and will occasionally prove of great value.

In concluding the subject I will say that if the nasal examination and treatment advocated be made in the class of cases here indicated, I feel assured that the successes resulting from treatment will be greater than in the past, and unexpected and gratifying improvement will sometimes occur in cases that had failed to respond to one's best energies.

CRIMINAL RESPONSIBILITY OF THE INSANE.

The subject of "the law in relation to the criminal responsibility of the insane" has once more been placed before the public for discussion by means of a paper read before the British Medical Association at Bristol, in August last, by Dr. Lionel Weatherly. The answers of the judges in 1843 to the questions put to them by the House of Lords form the basis of the legal position taken up in criminal cases where the plea of insanity is urged. The direction given by the judge to the jury in such cases is that to establish a defense on the ground of insanity, it must be clearly proved that at the time of committing the act the party accused was laboring under such a defect of reason from disease of the mind as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know that what he was doing was wrong. The corollary to this juridical direction is stated to be that if the accused were conscious that the act was one which he ought not to do, and if that act was at the same time contrary to the law of the land, he is punishable. Objection has been urged time after time to this statement of the position; and the righteousness of decisions in individual cases where the judge has directed the jury strictly in the sense here given, and where the jury have followed that direction, has frequently been called in question with such vehemence as to lead to a remission of the sentence. In other cases, as Lord Blackburn put it, "the jury have taken the bit between their teeth," and defied the judge's guidance as to the law by their verdict, asserting their belief in the prisoner's insanity and irresponsibility. "We mental physicians," says Dr. Weatherly, "maintain that the existing law is wrong, and that it is not in accord either with our practical experience or with the advance of mental science." This advance of mental science, whatever it may amount to, has at all events been the means of initiating the process of education which has made itself manifest in the minds of our judges in later years, and which has so largely tended to turn the fifty-year-old rigid dictum of "knowledge of right and wrong" into a merely traditional usage, supported in consonance with a practice which, as Sir James Stephen says in his "History of the Criminal Law," he has himself followed on several occasions, and which, he adds, no judge can be expected to do otherwise than follow until some more binding authority is provided. As a proof of this change of front, leaving out the idiosyncrasies and methods of a limited few of the judges, we cannot do better than quote Sir James Stephen's words: "I cannot help feeling, however—and I know that some of the most distinguished judges on the Bench

have been of the same opinion—that the authority of the answers (given by the judges in 1843) is questionable, and it appears to me that when carefully considered they leave untouched the most difficult questions connected with the subject and lay down propositions liable to be misunderstood, though they might, and I think ought to, be construed in a way which would dispose satisfactorily of all cases whatever." This statement was made in 1883, and since that date other judges have in some cases more or less openly expressed their difficulty as to the applicability of the ruling of 1843, or have modified its technical phraseology, while in other cases they have, in their summing-up to the jury, tacitly ignored the ruling. This being so, we are fully justified in holding that the legal test of responsibility in criminal cases where the plea of insanity is raised is not only insufficient, but is also misleading and capable of doing grave injustice if strictly adhered to. What is the remedy which Dr. Weatherly proposes for this state of things? He suggests the following as the questions which should be placed before the jury, and which the medical experts should be examined upon: 1. Was the accused at the time of the commission of the act with which he is charged, and before that time, laboring under such mental disease as to render him certifiably insane? 2. If insane, how far was crime the outcome of his insanity? If, as Dr. Weatherly says, the legal dictum is to be condemned for its want of latitude, we fear that the condemnation applicable to Dr. Weatherly's proposed questions is that they permit too much latitude. The risk in this case will come to be that in the search for insanity the question of mere criminality will be apt to be lost sight of. As the writer of the leading article in the *Times* of August 4th says—and not without some truth—the proposed change in the law "would throw upon the jury a task infinitely more difficult than it has to discharge at present." He goes on to ask, How is a jury to determine whether a man is "certifiably insane?" How is any man to attach a definite meaning to "certifiably insane?" "The phrase can only mean that a couple of doctors can be found to certify that in their opinion the man is insane." Under ordinary circumstances the meaning or the application of the phrase is simple enough, but its use in relationship to the complex issues that have to be determined in courts of law in criminal cases could scarcely fail to lead to confusion by its vagueness, for it is the duty of medical men to help the law not only to avoid hanging insane persons, but also to prevent sane and responsible criminals from evading justice on a false plea. In seeking for a solution of this great difficulty we, as medical men, must be prepared not to overlook any standpoint from which the mental elements of responsibility ought to be considered. The question is not a purely medical question any more than it is a purely legal one. Reverting once more to Sir James Stephen, we are glad to be able to quote from him in this relation the following important expression of opinion: "I believe that by the existing law of England those elements (so far as madness is concerned) are knowledge that an act is wrong and power to abstain from doing it, and I think it is the province of judges to declare and explain this to the jury." The admission of this element of "power to abstain" is, to our thinking, all-important and should never be lost sight of when the question comes up. In connection with the points raised in Dr. Weatherly's paper, which dealt very cogently and straightforwardly with the subject of the existing state of the law, influential subcommittees of the British Medical Association and the Medico-Psychological Association have been appointed to investigate the whole position of the case and to report. The subject will, therefore, be again brought to public notice in due course.

Salicylic Acid in Ringworm.

Salicylic acid is highly recommended as an application to ringworm. It may be used as an ointment, but is much better as a saturated solution in collodion. One application is often all that is necessary to effect a cure, but more may be necessary. The pain caused is not usually severe.—*Mass. Medical Journal.*

THE RELATION OF SEWER-GAS AIR TO TYPHOID FEVER.

Much light has recently been cast on the part played by sewer gas in typhoid fever infection. It has been shown that sewer air is as free from disease germs as ordinary air, but while it is probably not the carrier of typhoid germs, it is nevertheless an important factor in typhoid infection, by reason of its devitalizing effect on the human organism. Suffering under the debilitating influences of the poisonous gases sewer air contains, the natural powers of resistance possessed by man against parasitic organisms are lowered to such an extent that he falls an easy victim to their attacks and the disease is established.

The effect of inhalation of sewer gas has recently been investigated by Dr. Alessi through experiments on animals—rats, guinea-pigs and rabbits. In one of his experiments he exposed forty-nine rats to sewer gas, by means of boxes with perforated bottoms placed over drains. An equal number was likewise confined, but not subjected to the poisonous gas. After about two weeks both sets were inoculated with weak culture of the typhoid bacillus. As a result of this thirty-seven of those subjected to the noxious gases died, while but three of those not so treated succumbed. Out of seventy-two guinea-pigs subjected to poisonous gases, fifty-seven died after inoculation with the typhoid bacillus; in an equal number not subjected to the depressing influence of impure air, but inoculated with the same culture, none died. With rabbits the results were even more striking, for every one that had inhaled the gas and was inoculated died, and all that were kept in ordinary atmosphere were proof against the inoculations. The highest mortality in the animals occurred when they were inoculated during the first two weeks; those experimented with during the third week showed a mortality almost one-third less than those earlier treated, which would go to show that a certain degree of tolerance is established for the noxious substances when habitually inhaled.

These experiments are certainly very interesting, and the results obtained appear to clear up a subject not yet well understood. Before the conclusions, however, can be adopted as fixed facts, confirmation by other experimenters must necessarily be offered.—*Editorial Pittsburg Med. Rev.*

CHEMICAL, PHYSICAL, AND BACTERIOLOGICAL STUDIES UPON AIR OVER DECOMPOSING SUBSTANCES, WITH SPECIAL REFERENCE TO THEIR APPLICATION TO THE AIR OF SEWERS.

Dr. Abbott, at the Congress of American Physicians and Surgeons, said that under ordinary circumstances the difference between the chemical composition of the air from sewers and that of the atmosphere outside was very slight, and that, contrary to general opinion, there were comparatively few bacteria. It was also very commonly, but erroneously, supposed that sewer-gas was under very decided pressure. Professor Chandler had collected abundant evidence to the contrary. There was, moreover, not a single conclusive demonstration that the air of sewers stood in an etiological relation to many diseases for which it was popularly supposed to be accountable. The fact that the air in sewers was not under pressure, as a result of decomposition of the sewage, together with the fact that sewers were far from being air-tight, showed that the air of sewers was not likely to be driven out of the sewers under any great pressure. But little was known as yet regarding the nature of the bacteria found in the air of sewers. Experiments had been made at the laboratory, under his direction, with a view to determining the effect of the breaking of gas-bubbles on the conveyance of micro-organisms through the air. After endeavoring to simulate the natural conditions, it was found that such bubbling had but little influence of this kind. Bubbling was not a frequent condition in sewers, and, even should it occur, it was hardly conceivable that this would result in the transfer of micro-organisms from the sewer through the various branches and pipes leading to the houses. Then, again, if many pathogenic bacteria were present in the air from the sewers, those who worked in the sewers would show it in the effect on their health.—*Universal Medical Journal.*

THE LIBRARY TABLE.

BOOK REVIEWS.

Text-Book of Abdominal Surgery. A Clinical Manual for Practitioners and Students. By Skene Keith, F.R.C.S.Ed., assisted by George E. Keith. M.B., C.M. With illustrations. Philadelphia: J. B. Lippincott Co. 1894. Pages 508.

Based as this volume is to a large extent upon the immense experience of the celebrated Dr. Thomas Keith, whose early results—about 15 per cent. mortality after ovariotomy—were considered, at the time, so remarkable that they were described as "doubtful," and whose later results have been called "phenomenal," the authors have been able to present a masterly work upon the department of surgery that has assumed the foremost place within the last fifteen years. They have wisely grouped the subject under two main headings, namely, the surgery of the abdomen, and the surgery of the abdomen peculiar to women. In the former, after disposing of the points of general interest, such as tapping, exploratory incision, the examination of the withdrawn fluids, phantom tumors, the preparation for an abdominal operation, the technique of the operation, and the after-treatment, special chapters are devoted to a separate study of the peritoneum, the stomach, the intestines, the appendix, the liver, the kidney, and the spleen. The gynecologic section, while largely concerned with the ovaries and their pathologic conditions, includes also a consideration of the subject of uterine fibroids and the various modes of treatment that have been adopted, and a short discussion of the obstetric complications requiring surgical intervention.

The book is replete with valuable suggestions, and merits a careful reading. There are many points, however, which it shares in common with other English works, in which it differs radically from the teachings of the American writers. Notably is this the case in regard to the technique and after-treatment of celiotomy. The announcement that "the patient sits up in bed on or about the twelfth day, and gets up for the first time at the end of a fortnight," is widely at variance with the practice of the American abdominal surgeons, and, observed from our standpoint, there is given the subject an almost ludicrous aspect, when the authors proceed to apologize for this late (?) getting up, which, say they, is to "prevent, as much as possible, the risk of phlegmasia dolens." They seem to be happily oblivious to the imminent danger of ventral hernia, to which such a practice cannot fail to expose their patients. It would be interesting to inquire into the subsequent histories of patients subjected to this peculiar management of operative convalescence. Again, the minds of the skilled surgeons on this side of the water rise up in revolt when the advice is given to open the bowels of a patient convalescent from an acute peritonitis with doses of that abominable and nauseating mixture, the infusion of senna-pods; it seems like a glimpse into the methods of our medical forefathers of a less enlightened age that has now forever gone. Cauterization of the pedicle after ovariotomy is still favored, it being claimed that the only advantage the ligature possesses over the cautery is in the question of time. In this country, among progressive surgeons, the cautery, as far as abdominal operations are concerned, is relegated, along with the obsolescent carbolic spray, to the realm of surgical curiosities. Laparo-electrotomy (*sic*) is recommended among the surgical measures to be employed for the relief of obstetrical complications, notwithstanding the fact that this operation, with a mortality of fifty per cent. or more, is now looked upon as obsolete by the obstetricians of the world. Again, when we read that there is no especial tenderness attached to the tumor of an extra uterine gestation, we are led to the conclusion that the writers have fortunately escaped encountering many of these exceedingly painful and distressing cases.

Notwithstanding such peculiarities as these just enumerated, and which are largely sectional in their nature, the book is one of undoubted merit and will claim for itself more than the ordinary amount of attention from abdominal surgeons. D.

A System of Legal Medicine. By Allan McLane Hamilton, M.D., and others. E. B. Treat, 5 Cooper Union, New York. 1894.

In this book there is no evidence of an over-weening desire to get into the "book world," or of that effort which is technically called "book-making." All its chapters are written by men of scholarly attainments—men eminent in the chosen departments of their profession. The number of contributors gives to the style of the work an engaging interest. It is all it claims, encyclopedic, and more. Its special articles show that their authors thought into their subjects and not around them. The new material is made up of the new facts which modern research and studiously directed scientific experiment have evolved. The strength of the book lies in its carefully collated facts—living facts, vital to the present, not obsolete ones. The reader will be impressed by the clearness and conciseness of all the articles. They bear every evidence of great care and research, of honest, faithful and skillful work. In exposition of principles the work is logical, and is exact in its citations and deductions. Space will only

permit reference to a few of the important subjects treated:

"Medico-Legal Inspection and Post-Mortem Examination."

"Death in Its Medico-Legal Aspects."

"Blood and Other Stains."

"Hairs and Fibers."

"Identity of the Living."

"Homicide and Wounds."

"Inorganic Poisons."

"Alkaloidal and Other Organic Poisons."

"Toxicology of Ptomaines and Other Putrefactive Products."

"Medical Jurisprudence of Life Insurance."

"Legal Relations of Physicians and Surgeons," etc.

The article on the "Legal Relations of Physicians and Surgeons" would of itself make the book valuable to the medical profession. It condenses the law, as about settled in all the States, as it applies to physicians and surgeons in their relations to their patients and to one another. The author treats the subject under the important subdivisions of—

"Legislative Restrictions on Medical Practice."

"License and Examining Boards."

"Unprofessional Conduct."

"Legal Disabilities of Irregular Practitioners."

"The Contract for Fees."

"Who Is Liable for the Fee?"

"Professional Confidences."

"Sanctity of the Person."

"Criminal Offences," and other important departments of the general subject.

The book should receive a cordial reception from the profession. It contains very much the medical man needs to know. It will fill an important place in the professional library of the physician that is vacant without it. It should be kept in mind that the medical practitioner may be called upon at any moment to give evidence in a court of justice in a criminal case, and it is therefore important that he should know something of medical jurisprudence. R. P.

Chemistry: General, Medical and Pharmaceutical. Fourteenth edition. By John Attfield, F.R.S. Philadelphia: Lea Brothers & Co. 1894.

The writer's ideal of a work on chemistry for the use of students is one in which not only the *science* of chemistry is taught, but in which chemistry of every substance interesting the followers of medicine and pharmacy, is mentioned, according to its importance, at more or less length.

In the first part of the work chemical philosophy is considered; next comes the elements and the compound radicals, with their synthetical and analytical relations; then follows the chemistry of organic substances. The last chapters are the most interesting to the physician, for they treat of chemical toxicology, the chemistry of the urine, and likewise the microscopic appearance of morbid urine and the examination of calculi. O.

A Manual of Instruction in the Principles of Prompt Aid to the Injured. By Alvah H. Doty, M.D. Second edition. New York: D. Appleton & Co.

A manual such as this, is as valuable to the laity as to the trained nurse or the hospital steward. It contains an important chapter on hemorrhage, which is made valuable by cuts illustrating the lines of the important arteries and the methods of compressing the great vessels. The chapter on poisons is of great importance, but there are too many remedies for the various poisons. It is far better for those who may have to act in an emergency, to have a small stock of remedies which they can know well, than a whole store of indefinite ideas which only come to the mind to create confusion when an exigency arises. The author makes a mistake when he says that the symptoms of poisoning by mushrooms come on an hour after their ingestion; in certain forms poisonous symptoms do not make their appearance until ten or twelve hours afterward. Considered as a whole the manual is very well written.

J. O.

Treatment of Typhoid Fever. By D. D. Stewart, M.D. The Physician's Leisure Library. Geo. S. Davis, publisher, Detroit, Michigan.

The subject is well divided and considered under the head of prophylaxis, special and general; the specific and complications. The author departs from the common acceptation when he declares that "the Eberth germ . . . is not a specific micro-organism, but a modified or involution form of bacilli, all of which differ in form, size, and methods of growth." Otherwise the work is in perfect harmony with the most recent teaching.

Where to Send Patients Abroad for Water Cures and Climatic Treatment. By Dr. Thomas Linn. The Physician's Leisure Library. Geo. S. Davis, publisher, Detroit, Michigan.

This is a reprint of a small English book issued several months ago. Every physician who sends a patient abroad would do well to advise him to obtain a copy. The last chapter is especially valuable, for it contains an alphabetical list of maladies and the best places in Europe suiting the disease for which the patient is sent abroad.

Essentials of the Diseases of the Ear. By E. B. Gleason, S.B., M.D. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

This book has been designed by the author for the use of advanced students entering upon work in an ear dispensary, and for physicians who may care to acquire more than the meager outline of otology as ordinarily

furnished by the medical schools. The essentials of otology are stated as briefly and concisely as accuracy will allow.

The treatment employed is such as the long experience of an aurist has proven to be most successful.

List price $1.00; 89 illustrations in the text.

Essentials of Physics. By Fred. J. Brockway, M.D. Second edition revised. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

This is a book written for the use of the medical student in the early part of his course, and for the benefit of the hurried physician who may wish to bring to mind once more physical facts the exact principles of which may have escaped his memory.

Outlines of Obstetrics. By Charles Jewett, A.M., M.D., edited by Harold F. Jewett, M.D. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

The syllabus is designed for the use of the medical student in his course on obstetrics, and as a convenient hand book for reference to the practitioner. The subject of obstetrics is not treated exhaustively in this work, but it is accurately and concisely described.

Materia Medica Pharmacy, Pharmacology and Therapeutics. By W. Hale White, M.D., F.R.C.P., edited by Reynold W. Wilcox, M.A., M.D., LL.D. Second American edition. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut Street. 1894.

This is a work designed for the practitioner as well as the student.

It contains a separate list of all the recent non-official remedies, with their action and use, a fact which makes the book very valuable. Throughout the text the most important facts of each drug are brought out in heavy type or italics, so that the reader can pick them out without any difficulty. It is a well-arranged and accurate text-book, especially on therapeutics.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

IN THE PHYSICIAN AND SURGEON

for September appears a very interesting article on

Tyrotoxicon Poisoning,

by Dr. Luther S. Harvey.

In it he mentions the fact, not generally known, that cheese poisoning has been known for over one hundred years, and that the term tyrotoxicon was in use fifty years ago, at least.

Schmierkase and barschkase are said to be particularly apt to contain this poison on account of the manner in which they are prepared.

A very vivid record of two cases of poisoning has been found: "Two men made a breakfast of this same sort of cheese with bread and butter. One went immediately into the field and after a few hours noticed a heaviness of the head, anxiety and a painful feeling in the abdomen and pressure upon the chest. These symptoms became worse and were followed by dizziness and nausea. He was obliged to return to his home, where he was taken with severe vomiting and copious diarrhœa. After that the other symptoms disappeared and left only extreme weariness. The other man, who had breakfasted two hours later, came to dinner with tenderness in the abdomen and complained of dull pain and pressure in the head. With great difficulty he ate two plates of chicken soup, during which he turned alternately red and pale. Finally he rose from the table ashy pale, staggering into the front part of the house, where he fell upon the floor like a lifeless machine. He stretched out his hands and feet, his eyes being open, and from a large wound on the jaw caused by the fall came not a drop of blood. He was immediately raised from the floor; copious vomiting set in and the previously dry wound began to bleed. In this case diarrhœa did not occur and after the vomiting he experienced no unpleasant sequelæ."

Experimenting with poisonous cheese Vaughan found that a watery extract was poisonous, also an alcoholic extract.

In 1887 it was found that after treating an alcoholic solution of tyrotoxicon with platinic chloride, a violent explosion took place on evaporating it. Knowing that diazobenzol would under similar circumstances explode in the same manner, experiments were made with that substance, and it was found to be quite poisonous.

Diazobenzol is a transition putrefactive product. Hydrogen sulphide, heat, and exposure to the air destroy it, and this accounts for the difficulty in isolating it.

Vaughan claims that if the butyric acid ferment is prepared in the usual way, milk inoculated with it and allowed to stand for a few hours at the body temperature the poison will form. He is not prepared to say, though, that the cause of tyrotoxicon is the butyric ferment, but that it is usually present with it.

Dr. Harvey in testing some suspected cheese ate five grammes, and observing no effect, took two days later ten grammes, and suffered from vomiting and purging, apparently choleraic in severity, and recovered only after the free use of hypodermics of nitroglycerine, strychnia, and brandy together with paregoric, hot blankets, etc.

He concludes from this experience that scattered colonies of the microbes existed and the poison was intense in proximity to these.

Dr. J. R. Dodge reports a case of

Reflex Paralysis of the Organs of Phonation; Recovery.

The patient was a single girl of eighteen, who suddenly lost her power of speech. When seen there were no objective symptoms, and in spite of general, local and climatic treatment the condition remained unchanged. The patient married, and some time afterward—two years from the commencement of the trouble—was so frightened by some farm cattle that she screamed for help. Complete control and power over the voice remained from that time.

In an editorial on "Emotional Jaundice" several cases are cited where fright caused an intense and instantaneous jaundice. This he ascribes to a change in the relation between the blood pressure and the pressure in the biliary vessels. Normally, the biliary pressure is the greater. It is also known that the biliary vessels may occasionally contract.

Delayed jaundice following emotional excitement is probably due to an intervening digestive derangement.

Dr. David Inglis writes of the

Sequelæ of Diphtheria.

In diphtheria, he says, a poison similar to those formed in scarlet fever, rheumatism, measles, typhoid fever, small-pox, etc., is formed, and the after-effects of it lead to general destruction of the protoplasm with which it comes in contact and to the well-known sequelæ of diphtheria.

The kidneys are probably affected in almost every case, but to a less degree than in scarlet fever. The nervous symptoms are due to a multiple neuritis, but this differs from that due to alcohol, lead, etc., in being parenchymatous and not interstitial. It is, therefore, not followed by sclerosis, and when the regeneration takes place it is usually complete and is not apt to be followed by muscular atrophy.

When, however, the cells in the anterior spinal cornua are inflamed, a degeneration of the corresponding nerve-roots and an atrophy of the muscles supplied by these may result.

The oculo-motor and pharyngeal muscles are usually the first affected, and when visual defects follow they may usually be proven due simply to paralysis of the muscles of accommodation.

In this disease it is peculiar that symptoms may appear and progress in one part of the body, when cure is taking place elsewhere.

The danger in this poisoning lies in the probable paralysis of the cardiac and respiratory nerves. This may take place with scarcely any warning, hence the necessity of carefully observing the cardiac and respiratory rhythm and ordering absolute rest if there be the slightest irregularity.

The author records a case where the absence of symptoms in an indisposed child led to a complete examination, resulting in the discovery that palate, tonsils and pharynx were covered with the diphtheritic membrane.

The child seemed very slightly unwell, but died in eight hours.

Cod-liver oil and arsenic are preferred to galvanism; in fact, unless carefully used, galvanism is apt to retard rather than to help.

The diphtheritic poison may cause hemiplegia by degeneration of blood-vessel walls.

The very practical point is dwelt on that children should not be put to work nor study after a recent attack of diphtheria.

Other articles in this number are: "One Hundred Consecutive Obstetrical Cases," by Dr. W. S. Haughey; "The Importance of the Bacterium Coli, etc.," by Dr. Jules Simon; "The Pathology and Treatment of Diphtheria," by Dr. Collins H Johnston.

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY

for September. Dr. Ernest W. Cushing, Professor of Gynæcology at Tuft's College Medical School, contributes an interesting paper on

Abdominal Drainage.

The author compares the difference of practice among the English and German operators in respect to drainage after abdominal operations, and declares that the omission of drainage by the latter is based upon the use of a large incision and complete tying of all adhesions with catgut, and entire removal of all foreign matter from the abdomen without irrigation, the assistants being skilled, the preparations perfect, the operating-room ideal, the operator being a clinical professor of long experience and particular skill, and the patient being, on the average, robust and in good condition.

The reasons for employing drainage are stated to be the danger of a profuse sanguineous discharge, or even a serious hemorrhage, both of which the drainage-tube will carry off and in the case of severe hemorrhage will

give warning of the occurrence of the accident. The objections to the use of the tube are:

The use of a drainage-tube is a decided inconvenience.

If carelessly handled, it may become a source of secondary infection, with formation of exudates.

If incorrectly placed or left too long in position, it may fail of its purpose.

It may even, if wrongly used, be the origin of a fecal fistula, by pressure, or of a suppurating abdominal wound; or a sinus may remain in the track of the tube.

Its use greatly increases the necessity of skill and attention in the treatment, and adds to the discomfort of the patient for a day or two after the operation. By pressure on the intestine, unless removed in time, it may cause an obstruction even with fatal result.

The liability to subsequent hernia is said to be somewhat increased.

While the author fully recognizes the force of these objections, they are more theoretical than real in his opinion, and a fatal result from the use of the drainage-tube in competent hands is of extremely rare occurrence, and no such accident has occurred to him.

He gives the following indications for drainage:

1. The presence of freshly separated adhesions, or of voluminous pedicles, or of rents or incisions in the pelvic peritoneum which have required many stitches—in fact, of any condition which may lead to hemorrhage or to oozing of bloody fluid.

2. The fact that pus, or urine, or fecal matter, or the contents of cysts or much blood has escaped into the abdominal cavity, such a circumstance should always be followed by free irrigation with pure hot water and the use of drainage.

3. The perforation or incision of the intestine or bladder during operation, or a sloughy condition which makes it probable that perforation will occur. Even when an opening into these viscera found or made during the operation is carefully sutured, experience shows that patients often recover with a fecal or, as the case may be, a urinary fistula, who would presumably have died without drainage. Such fistulæ heal eventually under proper treatment.

4. The presence of masses of exudates, or of stiff walls of cavities from which diseased organs have been enucleated, which do not permit the intestines to snugly fill the pelvis and which would offer a cavity where fluid could accumulate.

5. Almost any condition, such as shock or weakness, which has required very rapid termination of a very difficult operation, in which case the abdomen will usually be full of hot water.

There are no special contraindications to drainage; the general considerations mentioned above prevent its use where it is not needed; but practically those operators who use the drainage-tube learn to trust in it, and where there is any doubt they drain.

A straight tube should be used because it is easier to clean, and sometimes it is important to turn it on its axis without removing it. It is also far easier to introduce and remove a strand of absorbent cotton or gauze through a straight tube than through a curved one, and often it is very desirable to turn the cotton-holding probe on its axis in order to wipe out the tube or to remove small clots of blood from the space of Douglas. The tube being straight should be well annealed, open at the lower extremity, and provided with a flange at or near the top. The lower two inches should be perforated with fine apertures, so small that the omentum or intestine cannot become entangled therein, and yet large enough to permit of the free passage of blood or secretions. The tube should be perfectly smooth inside and out. Cases that require drainage will usually require irrigation, which is best accomplished by pouring pure (distilled preferably) water into the abdominal cavity by means of a funnel and rubber tube with an end piece of glass or hard rubber having openings sufficiently large to permit of a free flow of water. Irrigation is to be continued till the fluid returned is clear or nearly so, making sure that opportunity is given for all clots to escape; then, without attempting to remove the water from the abdomen, the tube is to be carried to the bottom of the space of Douglas, and sometimes a second tube or a packing of gauze is required to drain some particular cavity with stiff walls. The abdominal wound is then to be closed around the tube, allowing the latter to project through that part of the wound where it will lie most easily. Excess of fluid may then be removed through a small rubber tube inserted through the glass drain, while a piece of thin rubber sheeting, or "dam," is stretched over the upper end of the tube, which projects through a small hole in the middle of the sheet and thus protects the dressings. The tube is to be kept empty by sucking the fluid out by means of a syringe with a long nozzle or one provided with a piece of tubing long enough to reach to the bottom of the tube. The author recommends that the tube be sucked dry every ten minutes after the operation, the interval being gradually increased. He also finds that it is not best to remove the glass drain under thirty-six hours after the operation, since the secretion sometimes diminishes after twelve hours, and then becomes quite free again during the period of reaction. When the glass drain is to be removed a rubber tube is introduced into it and the glass tube withdrawn, leaving the rubber tube in its place. A strip of iodoform gauze may be used in the same way. Whichever is used is shortened half an inch every morning, noon and night until it is all removed.

The author also describes the method of using the gauze drain of Miculicz, which in certain cases becomes necessary in addition to the glass drain. Particularly is this the case where there is free oozing from some points deep in the pelvis, or where it is desirable to prevent the intestines from falling into a cavity wholly or in part lined with a suppurating membrane, or where a perforation of the bladder or intestine has been

found or made, so that a fistula may reasonably be expected.

Drainage by the vagina receives little mention, as the author prefers to use drainage through the abdominal wound, while he concedes that it may be a useful procedure in cases of vaginal hysterectomy and sometimes in total extirpation of the uterus.

The same author also contributes a paper on

The Operative Treatment of Uterine Fibroids,

in which he sums up the results of his own experience as follows:

1. That electricity is useless and dangerous and has no place in the armamentarium of the surgeon.

2. That no method will compare with that of the extraperitoneal treatment of the stump in favorable cases—that is, where the abdominal walls are not too thick and the tumor can be lifted out so that a constrictor can be applied around the whole pedicle, including the uterine appendages; that the advantages of this method lie in its rapidity, in the short time during which the abdomen is opened, in the entire protection of the intestines from exposure and from handling, and in the absence of shock; that with proper care there need be no sloughing of the stump and little or no suppuration of the wound. This, then, for him is the operation of selection for the present, especially in private practice and in all cases where the patient is not strong and is ill prepared to withstand the shock of the longer operation required by other methods of treatment of the stump.

3. For the intra-extraperitoneal treatment he should always in future leave as little of the cervix as possible—dilate it, burn it, and drain it. This method is applicable to cases in which it is difficult to apply the former one, owing to the thickness of the abdominal walls, or rigidity of the pelvic floor, or the presence of dense adhesions requiring drainage. He sees little advantage to be gained from leaving any cervix; to avoid the great danger of sloughing of the stump, it must be amputated well below the level of the internal os after separation of the bladder from the cervix and ligation of the uterine arteries. When all of this has been done there is no difficulty or loss of time in removing all the uterine tissues. Drainage should usually be employed both through the vagina by gauze and by a glass tube at the bottom of the pelvis, as there is pretty sure to be free oozing.

The fact remains, however, and must never be forgotten, that for either of these methods of operation, by extra-intraperitoneal treatment or by total abdominal extirpation, the operation is prolonged from one-half an hour to an hour; during this time the pelvis is exposed to the air and too much handling; considerable blood may be lost, which runs in among the intestines; there is an added shock from the large amount of ether consumed, and the whole burden of proof is, in the author's judgment, still on those who would use these operations in cases which are suitable for the extraperitoneal treatment.

Dr. T. M. Burns, Instructor in Obstetrics at the Gross Medical College, Denver, Colo., etc., discusses "La Grippe During the Puerperal State," reporting several cases and presenting the various points by which the affection may be distinguished from puerperal sepsis.

Charles Greene Cumston, B.M.S., M.D., discusses "Sudden Death of Women from Placenta Prævia, with Remarks on Treatment." The author advises that the obstetrician keep on hand a quantity of sterilized tampons for use in such emergency. These tampons are saturated with iodol-glycerin, made in accordance with a formula given, and which he states may remain in the vagina for several days without giving any odor when withdrawn. Before introduction these are to be covered thinly with 8 per cent. carbolized vaseline, forming, when introduced, a sort of cement, which cannot be penetrated with blood. If the woman is in labor the tampons are to be used till dilatation is complete. The uterus must not be emptied too quickly and extraction of the fetus must be accomplished slowly.

Dr. Cumston also reports a clinical lecture delivered at the Charity Hospital, Paris, by Prof. Tilleaux on "Tuberculosis of the Rectum."

J. G. Carpenter, M.D., of Stanford, Ky., contributes an interesting paper on "Abdominal Surgery in the Country—Lives that could have been Saved by Early Surgical Interference," detailing a number of cases illustrating the conditions with which the surgeon has to contend in operating without the accessories considered absolutely essential in city practice.

A Clinical Study of the Effects of Inhalations of Chloroform and Ether Upon the Kidney.

Wunderlich (*Centralblatt fur Chirurgie*) has examined the urine of 100 cases of ether and chloroform narcosis. The urine was carefully examined berore and after, both microscopically and chemically. The investigations give the following results:

1. Those cases in which albumin is already present, the amount of albumin is markedly increased—that is, when ether is the anesthetic used.

2. Albumin is frequently seen after inhalations of chloroform, and seldom when ether is used.

This albuminuria usually disappears in from twenty-four to forty-eight hours.

3. When chloroform is used, casts are frequently found in the urine, but seldom after ether.

The course of the albumin and casts is, in the author's estimation, an ischemia of the kidney, or an increase in the blood-pressure.

The author, in conclusion, says the so called "ether nephritis" may be excluded from medical literature.—*University Med. Magazine.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

The Diuretic Action of Diuretin.

Pawinski (*Zeitschrift fur klinische Medicin*) comes to the conclusion, from his observations, that diuretin does not act through its influence on the innervation of the heart, as does digitalis, but in an indirect manner. By an increase of the urine and diminution of the edema the work that the heart has to do is lessened, and hence its action made more of use to the economy.

The diuretic action of diuretin is often excessive, ten to twelve quarts being sometimes passed in twenty-four hours. The maximum action begins on the fourth or fifth day. The substance is indicated in heart disease, where digitalis fails to act or cannot be taken. He uses it in aortic regurgitations, where digitalis is sometimes badly borne, and in heart disease, where there is great irritability of the nervous system. Diuretin gives better results in heart disease where there is disease of the heart muscle than it does in valvular disease. In kidney disease it is of less value. It is most valuable, however, in high grades of intestinal nephritis, where there is high blood-pressure. Dose is about fifteen grains, ninety grains to be given daily. It is best given in solution.—*University Med. Magazine.*

Bismuth Subgallate or Digestive Ferments?

The present *furore* in favor of bismuth subgallate is likely to prove its worst enemy because its general use in all forms of indigestion will eventually create a reaction against it, causing it to fall into disuse. That the remedy is a useful one in certain forms of functional dyspepsia cannot be denied, but to be successful clinically the diet must be properly regulated, and with this proper precaution—although the writer has used the subgallate quite extensively during the past three months—the results have been but little, if any, more satisfactory than he has experienced with the same dose of bismuth subcarbonate.

Unfortunately, the profession has gotten into the habit of prescribing bismuth in the form of subnitrate instead of the subcarbonate, and the favorable results following the employment of the latter are not appreciable when the former is given. The reason for this is obvious, since the subcarbonate is an amorphous powder, while the subnitrate is a crystalline substance, and no matter what may be the amount of the dose it always enacts the *role* of an irritant. But even with the administration of subcarbonate, and the rule is equally applicable in the case of subgallate, one or the other of the digestive ferments should be added. In all cases the addition of either pepsin or pancreatin, or the simultaneous exhibition of malt extract, will materially enhance the bismuth effects, and we therefore submit this proposition to the profession in the firm belief that it will prevent much disappointment on the part of physicians and patients.

That bismuth preparations act as disinfectants in the alimentary canal is freely admitted, but that they stimulate or measurably improve the digestive function proper there is room for serious doubt, and it would be well, therefore, in estimating the therapeutics of the remedy to take into consideration the physical demands of the patient. With our superior pepsin preparations and the elegant pancreatic extracts now at our command, it seems the part of wisdom to consider the ultimate effects of indiscriminately prescribing the popular remedy of the day.

To give the present article a practical turn, the following formulæ are suggested as a marked improvement over the use of bismuth alone in the treatment of dyspepsia and indigestion:

℞
Ext. nucis vomicæ..... gr. ¼
Pepsin pur..... gr. i
Bismuthi subcarbonas, vel bismuthi subgallas..... gr. iv

M. Et fiat Tab. vel Chart. No. i.

SIG.—Take one tablet or powder before and after eating.

℞
Ext. nucis vomicæ..... gr. ¼
Ext. pancreatini..... gr. iss
Bismuthi subcarbonas, vel bismuthi subgallas..... gr. iijss

M. Et fiat Tab. vel Chart. No. i.

SIG.—Take one tablet or powder before, and one two hours after meals.

The first of these formulæ will be found available when the fault lies with the stomach, the second when intestinal digestion is deficient. In the former case the diet should be regulated with a view to lessen the work demanded of the stomach; in the latter the starchy food-stuffs and fats must be diminished, the diet being principally of a nitrogenous character.—*The American Therapist.*

The Ancient Use of Sterilized Water.

Mr. Morris F. Davey (*Abergavenny*) writes: The following from Ragozin's *Media, Babylon and Persia* is interesting: "As soon as Susa became the principal capital of the Persian Empire, its river, the Choaspes, had the honor of supplying the kings with the only

drinking-water they would use. Kyros first instituted this custom, which was religiously kept up by his successors. 'Whenever the great king travels,' Herodotus reports, 'he is attended by a number of four-wheeled cars drawn by mules, in which the Choaspes water, ready boiled for use and stored in flagons of silver, is moved with him from place to place.'" The author says in a foot-note, page 319, "It is amusing to find so early an instance of this hygienic precaution—the boiling of water—which we are wont to consider so very modern."—*Diet and Hygienic Gazette.*

Resorbine: A New Ointment Base.

Ledermann (*British Journal of Dermatology*) reported to the Berlin Dermatological Society a base which is capable of traversing the skin after moderate rubbing in and which leaves a slight covering layer. It is made with some difficulty after a patented method by emulsifying pure almond oil and a little wax with water and a small percentage of other innocent but necessary vehicles. Resorbine can be mixed with all vegetable and animal fats. It is especially advantageous to add a little lanolin. Its use is indicated in all the hyper and parakeratoses, as ichthyosis and pityriasis, and in scleroderma, in artificial dermatites, ulcerations, rhagades, scabies. It combines well with Neapolitan ointment. The price is about the same as that of lanolin. —*Therapeutic Gazette.*

Inebriety as a Disease.

Dr. R. M. Phelps thus concludes an analytical study of this subject in the *Medical News:*

Our conclusions, then, would be something as follows:

1. We should, for the sake of clearness, not mingle or use interchangeably the words inebriety and irresponsibility; but in the cases in which it can clearly be shown to exist, we should make inebriety mean the drinking and irresponsibility the insanity so produced.

2. Disease should not be carelessly used to mean predisposition, or neurosis; nor should it be used to mean a disease-symptom unless so specified. But when unqualified it should designate a fairly well-defined entity composed of a group of symptoms with known or presumed pathology and causation.

3. Inebriety (excessive drinking) can then be stated to be not a disease, but as tending to produce various diseased conditions.

These conditions are quite general in character, but most notably seen in nerve-failure and brain-failure.

4. The predisposition varies in different persons and constitutes a temptation.

5. Irresponsibility is of varying grade, and the law does not necessarily follow these grades, but adjudges penalty, first, by the consequences of the act, and, secondly, for the safety of society.

6. In our opinion none of the early degrees of inebriety, as a rule, produces sufficient effect to be named disease or irresponsibility. This being true, even if there be a growing mental impairment, we would call the mental state insanity only when it would be so called if induced by other causative conditions.

Insanity as a disease is also subject to this same rule. The name is not applied to all mental changes, but only to those which have a considerable definition. Multitudes of mental impairments are not called insanity at all.—*Ohio Medical Journal.*

The Oxytocic Action of Salicylic Acid and Its Compound with Sodium.

Vineberg concludes an article on this subject as follows:

1. Salicylic acid and its compounds may be found useful in scanty and delayed menstruation.

2. They should not be administered to pregnant women who have a predisposition to abort or who suffer from menorrhagia and metrorrhagia.

3. Their administration should be watched carefully in all cases of pregnancy, and on the appearance of any "show," or anything resembling labor-pains, they should be discontinued.—*New York Medical Journal.*

The Production of Disease by Sewer Air.

Dr. A. Jacobi, of New York, in New York *Med. Jour.*, has lengthy and timely articles on the above subject. He shows that a sewer is not a good breeding-place for pathogenic germs. There is a deficiency of oxygen, an excess of carbonic acid, and many saprophytic germs. These conditions are opposed to the growth and multiplication of pathogenic germs. He further shows that scarlatina, diphtheria, pertussis and diarrhœal diseases have not been lessened in frequency nor in malignancy, by improved sewers. Further, the author does not think that disease germs are likely to be carried in sewer air. They are heavier than the air, and not likely to float in it. In order to float, these germs must be carried by dust. This is not what happens in the case of sewer gas. Dr. Jacobi thinks that putrefaction destroys pathogenous germs. He is also of the opinion that emotion and sentiment, rather than logic and science, have been ruling in this matter of infection by sewer gas. The atmosphere may contain both living and dead germs. They are frequently found in places that are infected; but are not as abundant in sewer air as in that of houses and school-rooms. Moist surfaces, such as the contents of sewers and sewer walls, do not give off germs into the air, unless when splashed, and then they are only carried by the sewer gas for a short time. Sewer gas may be very offensive and irritating, and in this way cause sore throats and catarrhal troubles. As the diphtheria germ is very ubiquitous, it may find a ready

nidus in this way. Putrefaction destroys specific germs. The more offensive the sewer air, the less likely would it be to contain the germs of diphtheria. The germs of typhoid fever and dysentery are not so readily destroyed by putrefaction. These diseases may arise from the exhalations from cesspools, etc., but very seldom come from sewer air. It is therefore the chemical poisons and not the germs that are to be guarded against in the drainage of houses and streets. —*Dominion Med. Monthly.*

Diagnosis of Habitual Headaches of Nasal Origin.

Dr. J. Scheinmann, of Berlin, claims that habitual headache very frequently is of nasal origin. Even in neurasthenia and hysteria he says that headache may be only due to some local nasal affection, and not be a single symptom of the total symptom complex. Grave diseases of the nasal cavities and their appendages may exist for a long time without the patient noticing them, while his headache is terrific, and only by the nasal symptoms becoming more distinct is the attention of the physician called to the true source. Neurasthenics are more easily affected than healthy subjects by these nasal irritations; often their headache is of local origin, and they will be frequently relieved by appropriate local treatment. Most patients with swelling of the mucous membrane of the turbinated bones suffer from more or less headache, and hence, where no known cause can be discovered in a case of headache, he advises examination of the nose, in hysterics and neurasthenics as well. Polypi are also a cause. The pain originates at the root of the nose, and radiates into the eye or the temple, or there is a constant dull pressure over the root of the nose, which often is associated with dull headache. Especially in cases of catarrh, with hypertrophy of the mucous membrane of the turbinated bones, is there a distinct listlessness and inability or loss of desire for mental exertion. Empyema of the maxillary is often accompanied by headache on the corresponding side, and at the root of the nose. There is a constant sensation of pressure at the root of the nose, and often severe neuralgic pains in the frontal region.—*Berliner klinische Wochenschrift—New York Med. Times.*

Treatment of Diabetes with Fluid Extract of Jambul E Cortice.

Dr. Lenne (*Therapeutische Monatshefte*), who had previously reported encouraging results from the use of powder prepared from the fruit of *Syzygium Jambolanum*, has now tried the fluid extract of the bark, according to the method proposed by Vix. Fifteen grains were given in water three times a day from one to two hours after meals.

On February 14th to 15th the patient passed 4,250 cubic centimeters urine, specific gravity 1034, containing a trace of albumin; 5.1 per cent. sugar (216.75 grammes); 3.1 per cent. urea (131.75 grammes); large amount of acetic acid.

Under treatment the patient's weight increased from 43.950 kilogrammes to 45.300 kilogrammes on March 17th. The volume of urine at that time was 3,000 cubic centimeters; the specific gravity, 1031; the percentage of sugar, 8.6 (108 grammes); the percentage of urea, 2.6 (78 grammes). The diminution in the amount of sugar was, however, not constant, reaching as high as 5.3 per cent. on February 22d and again 4.5 per cent. on March 16th. Lenne concludes justly that not the slightest influence of the agent upon metabolism can be recognized. For his part, he thinks that the fluid extract from the bark exerts just as little influence upon the sugar-excreting process of diabetes as does the powdered fruit.—*Therapeutic Gazette.*

A New Treatment of Pulmonary Tuberculosis.

Dr. Cohn, of Hamburg, has found ichthyol very useful in the treatment of pulmonary tuberculosis. He administers the drug in the following form:

℞ Ichthyolis..... } of each, 5 drachms. M.
Aq. destill..... }

The patient begins to take 4 drops of this solution thrice daily, and then the dose is increased by 1 drop daily until the maximum amount of 40 drops three times a day is reached. The best time of administration is before meals. Generally speaking, patients become readily accustomed to the disagreeable taste of ichthyol, but a mouthful or two of black coffee is very efficacious in removing the taste. The ichthyol is said to be very far superior to creasote or cod-liver oil.—*Medical Press and Circular.*

The Treatment of Jaundice.

Dr. M. Alivia, of Viterbo, read a paper before the International Congress on this subject, of which the following were the conclusions:

1. Long-continued biliary stasis, comprising the secreting cells of the parenchyma of the liver and producing a certain anemia of the organ, markedly reduces, and sometimes suppresses, the secretion of the biliary acids. The gravity of the phenomena described under the name of biliary intoxication does not, therefore, depend upon the action of these acids.

2. The scarcity or absence of bile in the intestinal canal modifies very seriously the chemical processes there taking place.

3. One of the most common of the gastric changes in icterus is the suppression of hydrochloric acid secretion.

4. There is little or no loss of carbonate of sodium in these cases.

5. The reaction of the contents of the stomach is usually alkaline, less often neutral or faintly acid.

6. The physiological activity of the bile and of the pancreatic juice in the intestine is retarded.

7. The chlorides in the urine are increased, the reaction of the fluid is often alkaline, there is diminution of urea with an abundance of products of the aromatic series.

8. The more marked are these characters so much the more grave are the disease and its clinical manifestations.

9. Alkaline treatment does not modify these conditions. The effect of the acid treatment is, however, to diminish the chlorides, to restore the normal acidity of urinary reaction, to increase the excretion of urea, and to reduce that of the aromatic products; at the same time there is a progressive increase in the weight of the body.—*N. Y. Med. Record.*

Clinical Studies as to the Influence of Chloroform Inhalation Upon the Kidneys.

Rindskopf (*Centralblatt fur Chirurgie*) gives a report of ninety-three cases of chloroform narcosis. In thirty-one cases, albumin, casts, leucocytes, epithelial cells were found in the urine. In the majority of cases the urine clears up after seventy-two hours. The quantity of chloroform administered greatly influences the character of the urine; chloroform should be given drop by drop continuously.

No case should be repeatedly chloroformed every three or four days, as the kidneys will not have had sufficient time to recover.—*University Med. Magazine.*

Causes of Sexual Debility.

Dr. F. R. Sturgis gives the following summary of his views at the termination of a very instructive paper: 1. That the cases of sexual debility which are marked by imperfect erections and by premature emissions are usually, if not entirely, due to hyperæsthesia of some portion of the urethra. 2. That masturbation has very little, if anything, to do with it, beyond the fact that if indulged in to excess it may induce a tendency toward this hyperæsthetic condition, but this is no more marked in masturbators than it is in those persons who indulge to excess in the venereal act. 3. That organic stricture has little, if anything, to do with it; but that associated with this hyperæsthetic condition there is an irritable condition of the canal which produces spasmodic contractions of the urethra upon attempts to pass instruments, oftentimes during the first act of micturition and at the time of connection. 4. That varicocele plays no unimportant part in these cases. 5. That neuralgia of the testis, if a cause of this disease, induces it merely as a secondary consequence to the pain, which is one of the distinguishing features of this disease. 6. That tuberculosis, syphilis and gonorrhœa may also play their part, and should all be reckoned with in summing up the causes which may induce this peculiar and depressing condition of affairs.—*Gaillard's Med. Journ.*

Treatment of Epithelioma.

Darier (*La Medecine Moderne*) has obtained excellent results with the following dressing: First dry the ulcerated surface, then cauterize with any cautery—thermo-cautery, galvano-cautery, or, still better, chromic acid—and finally use a solution of 1 to 100 of methyl-blue, either in repeated painting or in interstitial injections. Recovery often follows at the end of one or two months. Abadie, from personal observation, believes that the chromic acid is unnecessary, and that the methyl-blue alone is effective. He points out that the improvement is often exceedingly slow, and months may pass without appreciable change, and this probably accounts for the fact that it has been abandoned by many practitioners.—*Therapeutic Gazette.*

A New Hospital Invention.

A new invention called the thermogen is now being tried in several of the English hospitals with marked success. The object is to sustain the heat at a uniform temperature when artificial means are required, and of course its use would be limited to hospitals or institutions where the necessary facilities are easily obtainable. The thermogen consists of a light quilt containing a coil of wire bent in the form of a gridiron, inclosed in insulating and non-conducting material, and imbedded in cotton, wool or other soft substance, with a silk or woolen covering. The heat is produced by the resistance of the coil to the flow through it of the electric current. A uniform temperature of about 150° can be maintained for any length of time, the heat being prevented from going above that by the melting of a fuse which instantly shuts off the current. In those houses lighted by electricity the quilt can be connected with the ordinary incandescent terminals, but the principal use of the quilt would be confined mostly to hospitals, during lengthened operations, or in those attended with hemorrhage. —*N. Y. Med. Times.*

To Abort Syphilis.

Bichloride of mercury (10 grs. to ʒj) painted on a chancre as soon as it appears, kills all specific germs, and there will be no systematic manifestation. Then you only have a local sore to heal. So says the *Medical Summary.*

Vomiting of Pregnancy.

A writer in the *Lancet* says: "I have not failed once for many years, by a single vesication over the fourth and fifth dorsal vertebræ, to put an end at once to the sickness of pregnancy for the whole remaining period of gestation, no matter at what stage I was consulted. The neuralgic toothache, and pruritis pudendi of the puerperal condition yielded as readily, and to one application."

Diabetes.

Unschuld (*Berl. klin. Woch.*) draws attention to some of the less noticed symptoms in early diabetes. He quotes a number of illustrative cases in which the disease was masked by the presence of dyspeptic symptoms, nervous symptoms classed as neurasthenia, etc. Sometimes diabetes may quite accidentally be discovered. Here marked thirst and abundant urine were mostly absent. Frequently cramp in the calves is complained of, a symptom at present but little recognized. During the past eight years the author has found it in as many as 26 per cent. of his cases. In 1891 he found it 33 times among 109 cases. It most often occurs in the morning, but sometimes at night. If such cramps occur and the patient complains of weariness and weakness, the urine should be at once examined for sugar. These cramps may be present in all forms of diabetes, except in the acute disease occurring in young subjects. Massage and attempts at walking generally relieve the cramp. The cause is obscure; perhaps it is due to the diabetic toxins. The recognition of these cramps may lead to the early diagnosis of diabetes.—*British Med. Jour.*

SURGERY.

Compression of the Mammary Glands.

Verneuil (*Bull. et Mem. de la Soc. de Chir. de Paris*) advocates compression of the breast not only in cases of inflammation but also in cystic tumor. He has devised very light stays, made of perforated leather and laced behind. The pressure is easier to apply, more uniform, and more constant than when bandages are used. The patient herself places layers of wool, gradually increased in thickness, between the breast and the apparatus. Verneuil insists that operation is rarely needed in cystic disease of the breasts. He has treated by alkalies, arsenic, and compression two patients who had undergone amputation of one breast, and asked him to remove its fellow. In both cases the remaining breast was cured. He also cured by compression a bad case of hypertrophy of the breasts in a girl of eighteen, where amputation had been proposed.—*British Med. Jour.*

Immediate Repair to Injuries of the Pelvic Floor.

Dr. George M. Boyd reports in the New York *Journal of Obstetrics and Gynecology* 721 cases of completed labor with 117 injuries of the pelvic floor, and in some of these cases, fearing rupture in the perineum or elsewhere, he has been ready to operate and in most of them he operated at once. His conclusions are:

1. As every obstetrical case is greatly a mathematical problem, so is the safety of the pelvic floor; if the passenger is too large for the passageway (something must give), a tear, either vaginal or perineal, will follow.

2. As it is our duty to study all obstetrical cases before labor by palpation and pelvimetry, just as much is it our duty to examine the perineum and vagina after labor.

3. That having any injury to the pelvic floor, it should be at once repaired, and a good method to follow is to perform the operation under constant irrigation, using sterilized Chinese silk for sutures, and avoiding infection of wound by placing the stitches without inserting the finger in the rectum.—*Maryland Med. Jour.*

The Significance of Anuria After Surgical Operations.

We not infrequently hear it said that the case would have done superbly after operation "had not suppression of the urine" set in and cut off life.

This assumption in the vast majority of cases rests on a fallacious foundation, without a shadow of proof to sustain it. Cause is confounded with effect. A capital operation has been performed, a limb has been amputated or a serous cavity opened.

Profound mental shock follows, or acute surgical fever succeeds, the heart's action is tumultuous, the pulse becomes thready and excretion of the urine ceases. This latter phenomenon is always one of serious omen under these circumstances, not because it implies that any pathological changes whatever have seized on the secreting elements of the kidney, but that peripheral death has commenced. The blood-current steadily diminishes in volume; the secretory glands cease to act through want of circulatory supply.

We will observe for some time before the end comes that the lachrymal glands are deficient in action, so that the orbital conjunctiva and cornea become dry and hazy, the tip of the tongue is cool and the mouth dry.

No! suppression of the urine is rarely if ever *per se* a post-operative cause of death. It is simply an evidence of vascular stasis, following on a sinking of the vital powers—a consequence and nothing more.

This term, together with the more modern meaningless makeshift, "heart-failure," should go in the same category, for they both serve as an excuse and cloak for ignorance and nothing more.—*Editorial in Times and Register.*

Indications for Tracheotomy.

Cnopf (*Munch. Med. Woch.*) says that when membrane is present in the larynx two factors have to be reckoned with: (1) Irritation of the respiratory centers and (2) narrowing of the larynx. Since the upper lobes of the lungs are under favorable conditions as regards inspiration, and the lower lobes as regards expiration, distention occurs in the former, atalectasis in the latter. The author's observations extend over 130 cases of laryngeal obstruction in children. On admission the position of the diaphragm was marked out on the chest behind and subsequent variations noted. In 67 cases the diaphragm stood at the tenth rib in 3 cases, at the eleventh in 13, under the eleventh in 13, and at the twelfth in 38. The deepest position of

the diaphragm was thus observed in a majority of cases, and this at all ages. In 112 out of 126 the deep position was noted by the third day, and usually it was present on admission. In tracheotomized cases carefully observed the position of the diaphragm was rapidly raised one space in 12 cases and two spaces in 13. In only 4 cases did the diaphragm remain at the same level after tracheotomy. The position of the diaphragm is thus a measure of the laryngeal stenosis. The question of vesicular breathing and of the pulse must be considered, but with the arrival of the diaphragm at its deepest position the time for tracheotomy has come.—*British Medical Journal.*

HYGIENE.

Poisons on Fruit.

There has been much discussion of late concerning the danger of poisoning from eating fruit which has been sprayed with salts of copper or arsenic to destroy insects or fungi upon the plant.

It is stated that experiments have been carried on for two years at the Michigan Agricultural College with a view of finding out the truth in the matter.

The important question is: Do the poisons penetrate the skin of the fruit? The tests have shown that copper sulphate has passed into the body of the pear, though more of the solution remained upon the skin. If this peel is not a protection, what can be said of the thinner skins, like those of the plum, the cherry, berries, etc? Dr. Kedzie, who made the analyses, says that horticulturists often use much larger quantities of the poisonous solutions than are necessary to destroy the life of the fungi; one-half or even a third of the quantity generally used would be enough.

It is not safe to eat fruit which has been sprayed with any poisonous salts, for while the poison received into the system from one pound might not be harmful, if no more were taken, repeating the dose may in time result in slow poisoning.

And how are people in the cities to know whether or not their fruit has been sprayed?—*Sanitarian.*

PHYSIOLOGY.

The Migration of the Ovum to the Tube.

Lode, *Archiv fur Gynakologie*, has investigated this interesting subject by a series of experiments upon guinea-pigs. In one experiment he injected fine coal particles into the peritoneal cavity. The animal was killed thirty-six hours afterward and the coal particles were detected in both tubes. In a guinea-pig four months old, in which the sexual organs were not yet fully devoloped, the particles were found only in the fimbria. In another series of experiments he used the ova of the ascaris lumbricoides, as they were larger than the coal particles. The injections were made in the same way into the peritoneal cavity. The examinations of the guinea-pigs killed within a variable period of between thirty-six hours to seven days showed the presence of the ova in large numbers in about the middle portion of the tubes. In a few instances the ova had become glued together, forming a round mass fully the size of the natural ovum of the guinea pig. This was found in the same situation in the tubal canal. The author draws the following conclusions from his investigations:

1. The cilia of the tube of a guinea-pig have the power of setting into motion bodies the size of the ovum of the guinea-pig, providing that the animal has arrived at sexual maturity.
2. The tube is enabled to take up ova not only from the ovary, but also from the free peritoneal cavity. Hence the old theory may be discarded that it is necessary for the tube to be applied to the ovary in order to engage the ovum within its canal. The theory of transmigration—that is, the passage of the ovum from one ovary to the tube on the opposite side—receives new proof by the foregoing experiments.
3. The migration of the ovum is independent of the menstrual period, as none of the animals experimented upon showed any signs of rut, either while alive or at the *post mortem.*
4. The migration is not dependent upon coitus.
5. The ovum travels along the first part of the tube much more rapidly than along the remaining part of the tube.

Lode attributes but a small role in the propulsion of the ovum to the peristaltic movements of the tube.—*Archives of Gynæcology Obstet. and Pediatrics.*

The Use of Ice in Asthma.

Dr. Sangree has succeeded in cutting short a spasm in a severe attack of bronchial asthma by applying ice over the course of the pneumogastric nerve at the root of the neck. Five minutes after the application the spasm relaxed completely, and the patient slept, after having been four days without sleep.—*Bul. Gen. de Therapeut.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM OCTOBER 14, 1894, TO OCTOBER 20, 1894.

Leave of absence for one month, with permission to apply to the proper authority for an extension of one month, is granted Captain Eugene L. Swift, Assistant Surgeon, Fort Yates, N. D.

By direction of the Acting Secretary of War, so much of paragraph 1, S.O. 233, A.G.O., October 4, 1894, as directs First Lieutenant Isaac P. Wane, Assistant Surgeon, to report to the commanding officer Camp Eagle Pass, Texas, after his relief from duty at Fort Supply, is so amended as to direct him to report in person to the commanding officer Fort Clark, Texas, for duty at that post.

ORIGINAL ARTICLES.

THE CHEMICAL RELATIONS OF THE STOMACH CONTENTS DURING NORMAL DIGESTION.

DR. F. PENZOLDT.*

(*Deutsches Archiv fur klinische Medicin*, Sept. 14, 1894.) Condensed translation by A. L. BENEDICT, A.M., M.D.,† Buffalo, N. Y.

TRANSLATOR'S NOTE.

For the sake of abbreviating an article of twenty-six closely printed pages, the valuable series of experiments collected by Dr. Penzoldt have been rearranged, briefly described once and thereafter referred to by number. The expressions, "emptying of stomach," "close of digestion," etc., refer always to the completion of gastric digestion by the passage of food through the pylorus. Any statement that may seem ambiguous will, I believe, be explained by reference to the general heading. For example, *free acid* under A signifies free hydrochloric acid; *reaction* or *test* under C means the copper reduction test for sugar. Much under the headings B, C and D will be unintelligible without referring back to the particulars of the tests given under A and designated always by the same number. "P. C." means *post cibum*—after the meal. It must be remembered that this article deals only with normal digestion. Except some obvious deductions, nothing of importance has been sacrificed in the translation, despite the condensation. A. L. B.

* Director of Medical Polyclinic at Erlangen.

† Lecturer on Digestive Diseases, Dental Department University of Buffalo.

A.—TIME OF APPEARANCE OF FREE HYDROCHLORIC ACID IN GASTRIC DIGESTION.

(1) Gigglberger's experiments with 200–250 grams of meat.

Brain and calves' thymus, 1 hour P. C.; average continuance of test, 2 hours, 50 minutes (3 cases).

Pigeons and chickens, 2 hours P. C.

Calves' feet, partridge, roast beef, beefsteak, lamb, hare, beef tongue, 3 hours P. C.; average continuance of test, 3 hours, 50 minutes (12 cases).

Sliced raw ham, 3 hours P. C.; test slight or wanting.

(2) Experiments of assistants of Penzoldt with 250 grams of beefsteak (22 experiments).

In 20 cases free acid first appeared between 2 and 3 hours P. C.

In one case free acid first appeared 1½ hours P. C.

In one case free acid first appeared 2½ hours P. C., then disappeared till 4½ hours P. C.

In this series the average duration of the free acidity was 1¼ or 1½ hours, the minimum (each of two cases) being ½ hour, the maximum (one case) 2¼ hours. The free acidity persisted till the emptying of the stomach in five cases, till ¼ hour before this time in nine cases, till ½ hour before this time in four cases. In two cases the acidity disappeared an hour before the close of gastric digestion and in two ¾ hour before. Thus, on the aver-

age, the free acidity persisted till 20 minutes before the emptying of the stomach.

(3) Prager's twelve experiments with 100 grams of meat.

Beef sausage, warm roast fowl, 1 hour P. C.
Cold beefsteak, 1½ hours P. C.
Rare, warm broiled steak, raw and cooked ham, bacon, 1½ hours P. C.

In all these cases, the free acidity persisted till the close of digestion, the duration of acidity being in eight cases, 1¼ hours; in two cases, 1¾ hours; in one case, 1 hour; in one case, 2½ hours. Thus the total duration of gastric digestion was in most cases about 2½ hours.

(4) Hensel's experiments with roast beef to determine the delay of free acidity by increasing the quantity of food.

100	grams,	free	acid	appeared	1 hour	P. C.
200	"	"	"	" 4–4½	"	"
250	"	"	"	" 5½	"	"
300	"	"	"	" 6	"	"

(5) Walther's 16 experiments with 200 grams of fish; average time of digestion for the whole series, 3½ hours.

11 cases, free acid appeared 1 hour P.C.
2 cases, " " " 2 " "
1 case (salt herring), no free acidity.
2 cases (carp and bloater), acidity only temporary.

The acid, having once appeared, remained for 2–2½ hours, except as stated above.

(6) Five other similar experiments by Walther. Free acidity occurred at an average of 2 hours P. C. and lasted for a brief period. In another case it was entirely absent.

(7) Prager's seven experiments with 100 grams of egg, stomach contents expressed ½ hour P.C. and every quarter hour thereafter.

No free acid found till 1 hour P. C.; it then persisted till ¼ hour before the close of digestion; digestion occupying 1½–3 hours.

(8) Croce's 20 investigations with 150 grams of vegetable food, the first test being made 1–1½ hours P. C.

Albert biscuits, acidity lacking 1 hour 25 min. P. C., present 1 hour 55 min. P. C.

Stewed peas, acidity lacking 1¼, 1¾, 2¼ hours P. C., present 2¾ P. C. Total duration of digestion, 4 hours 5 min.

Stewed lentils, acidity lacking 2 hours 5 min. P. C., present (weak) 2 hours 35 min. P. C., present (strong) 3 hours 10 min. P. C. Total duration of digestion, 4 hours 15 min.

Green beans (no statement as to acidity) required over four hours for digestion. Other vegetables required less than four hours.

(9) Prager's 14 experiments with 100 grams of different breadstuffs. Free acid was always found 1 hour P. C., and it persisted till ¼ hour before the close of digestion. It was not examined for before 1 hour P. C.

(10) Twenty-five experiments by six investigators, using 70 grams of wheat roll and 200 grams of tea.

Free acid always found 1 hour P. C. In two cases only was an earlier test made, when it was found ¾ hour P. C. In all cases it persisted nearly or quite to the close of digestion.

(10[1]) Langguth's three experiments with 70 grams of white bread. Free acid found ¼ hour P. C.

(11) Hensel's five experiments with 70 grams white bread.

5	minutes	P. C.	no	acidity			
20	"	"	"	"	in	2	cases
20	"	"	weak	"	"	3	"
35	"	"	no	"	"	1	"
35	"	"	weak	"	"	1	"
35	"	"	marked	"	"	3	"
50	"	"	"	"	"	5	"

(12) Six similar experiments by Prager. Acidity found 40–55 minutes P. C.

(13) Hensel's experiments with different amounts of dry Albert biscuit [cf. (4)].

50	grams	free	acidity	1½	hours	P. C.
100	"	"	"	1½	"	"
150	"	"	"	2	"	"
200	"	"	"	2½–3	"	"

In all cases, the acidity persisted till ¼ hour before the close of digestion.

(14) Hensel's experiments with Albert biscuit and 200 grams of water [cf. (13)].

50	grams	Albert	biscuit,	acidity	¾	hour	P. C.
200	"	"	"	"	2½	"	"

These experiments showed that the addition of water hastened the appearance of free hydrochloric acid half an hour.

(15) Prager's experiments with 200 c.c. of liquids, tests made every quarter of an hour.

Water charged with CO_2, acidity appears ¼ hour P. C., lasting till ¼ hour before emptying of stomach into intestine, which occurred 1–1½ hours P. C.

Tea and black coffee.....	acidity	appears	¼	hr.	P. C.
Watery preparation of cocoa	"	"	1	"	"
Coffee with 5 c.c. cream.....	"	"	1	"	"
Cocoa with milk.....	"	"	1½	"	"
Milk (first investigation ½ hr. P. C.), 7 out of 9 cases.....	"	"	½	"	"
Milk (first investigation ½ hr. P. C.), 2 out of 9 cases.....	"	"	¾	"	"

In the above list the stomach emptied

itself 1½–2½ hours P. C., the acidity persisting till just before this time.

Leube-Rosenthal peptone solution	acidity appears	¼–½	hr. P. C.
Bouillon, Valentine's meat juice, Kemmerich's peptone, Dennayer's "	"	½–¾	" "
Liebig's extract, Weyl's casein-peptone, Pool's gluten-peptone	"	1–1¼	" "
Sparkling and Moselle wines	"	¼	" "
	"	¼	" "
Beer, pfalzer, Rhine wine, Ofner	"	½	" " (trace) (marked)
Sweet wines, Malaga, Marseilles	"	¾	" "

In this whole series the acidity persisted till just before the emptying of the stomach.

(16) Krieger's experiments with 500 c.c. of liquids.

Water, CO_2 water, syrup, clear tea, coffee, cocoa, with or without sugar, acidity appears ¼–½ hour P. C., and persists till the emptying of the stomach, 1–1½ hours P. C.

Cocoa, with milk, free acidity ¾ hour P. C.

Milk, no free acidity; stomach emptied itself 1 hour P. C.

Sour milk, free hydrochloric acid 1¼ hours P. C.; stomach emptied itself 2 hours P. C.

Beer, white wine, free acidity ½ hour P. C.

Red wine, free acidity ¾ hour P. C.

Beer and wines left the stomach 1½–1¾ hours P. C.

(17) Hensel's experiments with different quantities of liquids [cf. (4) and (13)].

100 c.c. milk	free acidity	½	hour P. C.
200–300 "	"	1	" "
400–500 "	"	1½	" "
500 c.c. beer	"	½	" "

(Same as for smaller quantities, but weaker.)

500 c.c. water ..... free acidity ¼ hour P. C.

(Same as in (15) and (16).)

B.—ALBUMIN AND PEPTONE REACTIONS IN GASTRIC DIGESTION.

Albumin determined by acetic acid on potassium ferrocyanide. Peptone by biuret reaction with alkaline solution of cupric sulphate. The numbers in parentheses refer mainly to the same experiments as in A.

(1) No tests made before 1 hour P. C. Brain and calves' thymus (3 experiments), little or no albumin. Poultry, roasts, beefsteak, ham, etc. (10 experiments), albumin marked 1 and 2 hours P. C., weak or negative between 3 and 4 hours P. C.; peptone about the same, any difference being in the slightly greater persistence of peptone.

(2) Variable results in 5 cases. In 11 albumin was pretty constantly present 1–2 hours P. C., disappearing toward the close of digestion, which was completed after 4 hours or more.

(3) In three cases albumin was slight or absent 1 hour P.C. (not examined for earlier). In eight experiments the albumin test was positive 1 and 2 hours P.C., weak or negative between 3 and 4 hours P.C.

(18) Two experiments of Langguth with beefsteak showed a weak test for albumin ½ hour P. C., which later became plain but never marked. Peptone was present earlier than albumin.

(5) Albumin was apparent 1 hour P. C., weak 2 hours P.C., afterward was present only in traces if at all. Peptone was present till shortly before the emptying of the stomach. In three experiments with shell-fish, codfish and eels, the peptone test was weak in the second hour.

(7) Albumin was present from ½ to 1 or 1½ hours P. C. The precipitate was never heavy and after 1½ hours was a mere trace or altogether absent. Peptone, same as albumin.

(15) In this group of experiments were thirteen with 200 c.c. of milk (raw, boiled and sterilized). In three (including two with sterilized milk) albumin was not found in any of the quarter-hour tests. In ten cases albumin was found ½ and ¾ hour P. C., afterward it was absent. Peptone was present ½ and ¾ hour P. C., weakening after one hour P. C., entirely absent toward the close of digestion.

(19) Twenty-four reliable experiments of Croce with about 200 grams of vegetable food.

Apples, cherries, cucumbers, turnips, cauliflower salad; albumin never found.

Lentils, spinach, "rape-cabbage," beans, radishes, tapioca, asparagus, some preparations of potato and some breadstuffs; albumin sometimes weak, sometimes absent.

Cakes, rice, cauliflower greens; albumin marked in the beginning, then disappearing.

Stewed peas; albumin as well as peptone weak in the beginning, then very marked.

Peptone was always lacking after apples, cherries and radishes. Note the discrepancy with the albumin reactions. Peptone was weak or absent with asparagus and "potato-vegetables." Peptone was apparent early, later disappearing, with white bread, "potato-fritters," rice, spin-

ach, "rape-cabbage," beans, turnips, cauliflower greens. It was always apparent after taking cakes, "groat-bread," stewed potatoes, lentils, asparagus salad, cauliflower, tapioca.

(12) Albumin was present in the greater half of digestion, absent in the shorter latter stage. Peptone was present from one hour P. C. almost to the close of digestion. (Thirteen experiments are referred to here, instead of six.)

(10) Albumin usually found 1 hour P. C., persisting till 1½ or 2 hours P. C., exceptionally till the end of digestion. Peptone was present as in (12).

(10[1]) Albumin distinct ¼ hour P. C., weak after ¾ or 1 hour P. C. Peptone weak but apparent ¼ hour P. C.

(13) No difference was found in the relation of albumin to the amount of food taken, except that with milk the test which was entirely absent for small quantities became apparent with larger quantities (cf. (15) B). The duration of the peptone test varied directly as the quantity of food for meat, milk and cakes.

100 grams meat, peptone test persisting till 2 or 3 hours P. C.; average duration of digestion 3½ hours.

300 grams meat, peptone test persisting till 6½ hours P. C.; average duration of digestion 7½ hours.

C.—THE GLUCOSE REACTION.

Both Tremmer's test and the ordinary application of the alkaline solution of cupric sulphate were used. These reactions always failed in substances free from starch and sugar. In all 107 experiments were made.

(19) Stewed potatoes, potato cakes, peas, lentils, tapioca, black bread, cherries; sugar present throughout digestion.

"Potato vegetables," rice, spinach, "rape-cabbage," cakes; marked test early, less or none toward the end of digestion.

Cauliflower greens, yellow turnips, test weak or negative.

With all the foregoing except cherries starch was shown by the iodine and potassium iodide solution to be present.

Asparagus (3 experiments), cauliflower (2 experiments), beans, cucumber salad, radishes, apples, sugar test negative.

(9) Sugar always present at the end of one hour (not examined for earlier), disappearing on the average ¾ hour before the end of digestion (minimum ¼ hour, maximum 1¼ hours before the end of digestion).

(10) Kauderitz *et al.* with 70 grams of white bread and tea. The sugar disappeared, on the average, ½–¾ hour before the emptying of the stomach.

(10[1]) Sugar always present as early as ¼ hour P. C., becoming much less after 1 hour P. C.

(13) The more breadstuff was taken the longer the sugar remained, but it usually disappeared 1 hour before the close of digestion.

50	grams	cakes	negative	after	1¼	hours	P. C.
100	"	"	"	"	2¼	"	"
200	"	"	"	"	3	"	"

The sugar test was weaker and less persistent if 200 grams of water were taken with the cakes [cf. (14) A].

D.—THE UNRELIABILITY OF UFFELMANN'S TEST FOR LACTIC ACID.

A dilute solution is made of ferric chlorid and carbolic acid. This has the color of amethyst. Lactic acid and lactates change it to a greenish-yellow.

Penzoldt says that the reaction is interfered with by hydrochloric and lactic acid, and that other substances, such as alcohol and cane sugar, may give the same reaction. [I have verified this statement. A. L. B.]

(3) Lactic acid test found from 1 hour P. C. (not examined for sooner) till the end of digestion. After beefsteak the test was weak, early and toward the close of digestion.

(2) Two experiments by Moch in this series. Lactic acid test first appeared 2–2½ hours P. C., remaining till one hour before the close of digestion.

(21) Langguth in two experiments with beefsteak found the test in the first hour; with eggs the reaction was not marked except at the height of digestion.

(10[1]) The reaction first appeared ¼ hour P. C., becoming weak 1 hour P. C., or it was weak throughout the first hour of digestion.

(10) Test found from 1 hour P. C. (not examined for sooner) almost to the close of digestion.

(9) Reaction marked and persistent if food was taken dry; variable and not marked till the close of digestion if food was taken with tea.

(8) After eight vegetable foods, including breadstuffs, rice, etc., the reaction was present from 1–1½ hours P. C. to the end of digestion.

After ten vegetables, including peas, lentils, etc., it was marked early in digestion. With carrots and asparagus the reaction was weak, and with cauliflower and tapioca entirely absent after the beginning of digestion.

(4), (13), (17) No difference was found due to the quantity of food, except that as digestion was longer the duration of the lactic acid test was greater.

(15) Ten experiments each with milk and a group of non-alcoholic beverages (soft drinks) showed a variability in the lactic acid test which, however, was usually more apparent in the latter half of digestion.

In nine experiments with alcoholic drinks and eleven with peptone solutions, the test was pretty constantly found from ¼ hour P.C. till the close of digestion.

(22) Cohn v. Mehring 1 hour after a meal of 150 grams of black bread found 1.6 per cent. of hydrochloric, 2.07 per cent. of lactic acid.

(23) Penzoldt found the Uffelmann reaction in the wash-water after lavage of the empty stomach. Having obtained many liters of wash-water, he endeavored to precipitate zinc or calcium lactate, but failed utterly. He naturally concludes that the Uffelmann test occurs in the absence of lactic acid and fails when lactic acid is presumably present, also that even if the test always indicated lactic acid, it would be practically useless on clinical grounds.

GENERAL CONCLUSIONS.

A longer gastric digestion corresponds with a greater bulk of food, a higher proportion of albumin and, consequently, a later appearance of free hydrochloric acid.

According to Moritz, albumin fixes this acid till the ratio 1:8 or 1:12 is exceeded.

Lack of hydrochloric acid depends on (*a*) a large amount of albumin, (*b*) of ash, (*c*) a peculiarity of the albumin or of the connective-tissue inclosure. (*a*) and (*b*) are illustrated by the fact that cauliflower, containing 2½ per cent. of albumin, allows free acidity 1 hour P. C., while lentils, containing 25.7 per cent. and three times as much ash as cauliflower, allow free acidity only after 3 hours. (*b*) is not so important as (*a*). In illustration of (*c*), calves' thymus, which contains a trifle more albumin than beef and decidedly more ash, absorbs only 9:1000 of hydrochloric acid, as compared with 20:1000 for beef, so that free acidity occurs 2 hours earlier with the former.

300 grams of beef allow free acidity five hours later than 100 grams; with the same amounts of milk, the difference is only ½ hour; with fluids nearly or quite without albumin, the delay is not noticeable.

There is both a relative and an actual increase in the duration of free hydrochloric acidity when (*a*) the percentage of albumin is lowered or (*b*) the bulk of food is diminished.

Food taken with water is more quickly digested than when taken dry.

2:1000 solutions of hydrochloric acid (the normal gastric strength) extract more soluble albumin from meat than does water.

The filtrate of milk artificially coagulated by hydrochloric acid contains no albumin, but soluble albumin is found in the stomach ½ hour P. C., hence the gastric juice must have a solvent action. Bread contains more soluble albumin than cooked meat; after the former, albumin is found ¼ hour P. C., after the latter ¾ hour.

Soluble albumin is not abundant during digestion, probably on account of concomitant absorption. In the last third of digestion it is absent, being instantly peptonized or absorbed.

Peptonization is concomitant with the dissolving of albumin; in fact, unless much albumin is present, peptone alone is found.

Peptones, and more particularly sugar, dissolved in water, are more quickly absorbed than the water itself.

Vegetables containing less than 10 per cent. of carbohydrates usually fail to give a sugar test in the stomach contents, probably from the rapidity of absorption. Foods after which the sugar test is always present for some time during digestion contain 20–50 per cent. of carbohydrates. Sugar is usually completely absorbed long before the end of digestion.

The best test meal consists of 70 grams of white bread with 200 c.c. of water, or milk alone. Meats are not suitable for the ordinary tests.

APPENDICITIS—REPORT OF A CASE.

FRANCIS A. WEBB, M.D., Fairford, Ala.

It is the object of this paper not to enter into a discussion of appendicitis, but to report a case that came under my observation, to show how difficult it often is to make a diagnosis, and to demonstrate the futility of medication in certain cases.

I was called July 13th, at 3 P.M., to attend G. C. K., white, male, age 7 years. On inquiry I learned that the child was attacked at 10 A.M. with violent vomiting and pain in the abdomen. The vomiting and pain had continued up to the time of my visit, in spite of a number of domestic remedies given by the mother. The boy, a fine healthy fellow, had been perfectly well up to the sudden attack that morning. On further inquiry I learned that the boy had eaten heartily of watermelon just before the attack, and had vomited quite a quantity of the seeds. The bowels had moved once that morning.

On examination of the abdomen I found that he complained of pain one inch to the *left* and just below the umbilicus—a localized pain increased on pressure. No swelling or tumor over this region. I examined carefully the right iliac region; result negative. There was no tenderness whatever over McBurney's point. Pulse, 100; temperature, 101° F.; tongue coated.

The case was regarded as one of indigestion, with probably a malarial element, and was prescribed for accordingly.

For the pain and nausea a hypodermic of morphia, gr. $\frac{1}{8}$, atropia sulph, $\frac{1}{100}$ gr., was given. Calomel, grs. iij, lactopeptine, grs. xv, divided in powders 3, were ordered to be given every two hours.

Quinine, grs. ij, at 6, 9 and 12 the next morning, also a dose of castor oil if the calomel failed to act.

The hypodermic relieved the pain and vomiting; the litttle patient was left comfortable and with a hope that all would be well after the medicine had acted.

Next morning (July 14th) the father called to see me and stated the boy was no better, had passed a bad night—the calomel had been retained, bowels had not acted, castor oil had been rejected, vomiting and pain had returned. He had not attempted to give the quinine.

He was instructed to return and give the child a stimulating enema of turpentine, egg and water, to repeat this if necessary until the bowels moved; also to apply a mustard plaster over stomach. A mixture of tr. cardamon comp., soda bicarb., aq. menth. pip., was ordered for the nausea.

I promised the father to be over (he lived some distance in the country) as soon as I could attend my morning calls.

The child was seen a few hours afterward, and at a glance it was evident he was very ill.

Countenance anxious, pulse 130, typical of peritonitis. Abdomen distended and tympanitic; pain now diffused; temperature 102° F.; vomiting constant; bowels obstinately constipated.

Two enemata had been given without any result.

It was clear that there was obstruction, but the cause, intussusception, volvulus, fecal impaction, appendicitis or worms, was the point to decide.

To relieve urgent symptoms, the hypodermic of morphia and atropia was repeated, ice-bag to abdomen, and measures *per rectum* to open the bowels. A full dose of sulph. magnesia was also given.

So long as the child was kept under morphia the pain and vomiting were in a measure relieved.

I remained with the child until 2 A.M., July 15th, failing to relieve him or get any movement on his bowels. My colleague, Dr. D. J. Spotswood, was called in consultation. We discussed the propriety of an exploratory operation, but decided that his condition was such that it was not warranted. We agreed to continue our efforts to remove the obstruction. Discontinued the ice-bag and substituted hot flaxseed poultices. We also washed out the stomach with a boracic acid solution by means of the stomach tube, and introduced four ounces of olive oil. The oil was retained and in a few hours afterward passed through the bowel; this aided by injections moved the bowels freely.

After this the child seemed better; tympanites, pain and vomiting were in a great measure relieved, so much so that

we were about to congratulate ourselves that the boy would recover.

The next day he was worse again; the vomiting returned, accompanied by the other bad symptoms.

He vomited during the day two very large round worms six or eight inches in length.

The family now felt sure the worms were the cause of all the trouble, and insisted that the child be dosed for worms.

Thinking perhaps the worms might be an element in the case, and to comply with the earnest wish of the parents, calomel and santonine was given, but without results.

The child continued from bad to worse, and died on the seventeenth day of his illness.

Autopsy six hours after death. The abdominal viscera only examined.

The abdomen very much distended with gas; also the intestines.

On section found a diffused, purulent peritonitis; adhesions everywhere.

The appendix at its extremity was gangrenous and perforated.

We found a hard fecal impaction (about the size of a bean) packed down in the extremity of the appendix and almost out through the perforation.

REMARKS.—The history of this case, symptoms and all, shows how difficult it is to make a diagnosis early.

It further shows the necessity for early operation, and how often conservatism proves impotent.

THE SPECIAL THERAPEUTIC VALUE OF INDIAN HEMP IN CERTAIN MORBID STATES.*

STEPHEN MACKENZIE, M.D.,† LONDON, ENG.

Much has been written on Indian hemp and numerous are the diseases in which it has been employed with success. Nevertheless it is much less frequently used than it should be. Several causes have contributed to this more or less complete abandoning of the drug by physicians, among the chief ones being the variability of its action, the occasional symptoms of poisoning which it has produced, and the ignorance of the fact that there is a certain number of diseases in which it is particularly useful.

According to my own experience, cannabis Indica is especially efficacious as an analgesic when it is desired to combat the element pain associated with spasmodic phenomena. It exercises a favorable action in all forms of headache, whether it be purely functional or be dependent upon an organic affection. Thus I have succeeded in controlling with Indian hemp the violent headaches of cerebral tumors. In these cases it may be equally as effective as morphine subcutaneously or it may be less active. It is able to abort an attack of migraine either at the beginning or after it has persisted for a certain time; with its prolonged use we are able to diminish the frequency and intensity of the attacks. Yet in the palliative treatment of a pronounced hemicrania it is, in general, inferior to antipyrine, phenacetine and trinitrine. As to nitroglycerine, this drug has often given me the best results in decreasing the number and intensity of attacks of migraine when administered, for a long time and in small doses, as suggested by Gowers. Finally, I have employed Indian hemp in the headache of chronic uremia; it may consequently be recommended to those physicians who fear to employ morphine in uremic subjects, a fear which I may say, in passing, I have never shared. But there is one particular form of headache in which the drug acts as an actual specific; this has been confirmed both by my own observation and those of my fellow-practitioners.

The variety to which I refer might be styled a continued or sub-continued type. It begins in the morning and persists during the entire day. It may disappear toward evening, but if the patient arise during the night he will feel it again. The pain is generally diffuse, extending through the whole head; it is dull and may become aggravated at times for several moments and last for weeks, months and even years. Without being violent enough to prevent the patient fol-

*Translated from *La Semaine Medicale*, No. 50, 1894, by F. H. Pritchard, M.D.

†Attending Physician to the London Hospital.

lowing certain occupations which do not require considerable intellectual effort, it constitutes a constant source of ill-health and distress. This form of headache is observed in both sexes, more frequently in young or middle-aged persons. Its etiology is obscure. Many of those affected present no signs of anemia, and even if this diseased state exist and be treated it will have no influence upon the headache. I have not been able to trace any relation between this variety and an excess of uric acid in the blood, and I have met with disappointment in trying to treat this headache by means of dietetic measures and the remedies ordinarily employed in uremia.

It is, however, easily cured with cannabis Indica, either alone or associated with other drugs to combat concomitant disturbances. I ordinarily employ the drug in the form of the extract, administering from 15 milligrams to 3 centigrams in pills morning and evening. If an amelioration follows I continue it in the same doses; but, on the contrary, if there is no marked improvement in ten to fifteen days I increase the dose to 6 centigrams of the extract in the evening and 3 in the morning. If these doses are still insufficient I prescribe 6 centigrams morning and evening. In cases which are particularly obstinate I elevate the dose progressively, giving preferably the stronger dose in the evening, until I obtain a decided amelioration or symptoms of poisoning. Each year I treat a large number of cases of continued or sub continued headache. From the numerous examples which I might present I shall select two cases which will illustrate the type.

In one, the patient, a woman aged twenty-five years, had been affected for about a year with a continuous headache which was especially located in the occiput. The pain, which was generally dull at times, presented periods of exacerbation, accompanied by nausea without vomiting. Sometimes she noticed a weakening of her visual powers, but she never had scintillations of light nor other subjective visual sensations. She was always cold, especially during the night. Her appetite was good; digestion was painful; there was besides constipation with distention of the intestines. Under the influence of Indian hemp, together with gentian and Peruvian bark, I had the satisfaction of obtaining in eight days a notable improvement which continued to increase, with a complete cure in one year, during which time the treatment was continued with perseverance.

The second case was that of a woman of forty-two years who had suffered for seven years from attacks of headache which had appeared after her last confinement, and would come on every eight to fifteen days. The seizure would last for two to two and a half days and occasionally longer. The pain was more severe in the evening than during the day; it was situated in the temples particularly. Beyond a sensation of tingling and heat in her eyes she experienced no other visual disturbances. In the course of years these attacks of headache whose etiology was very obscure increased in intensity. During the intervals her health was perfect, her digestion good and her stools regular. I prescribed the extracts of cannabis Indica and gentian. During the month which followed she only had a few slight attacks, which soon disappeared under the use of the hemp, to which I added, later, the bromohydrate of caffeine.

In the past twenty years, during which I have employed Indian hemp in this form of headache, I have had but few failures to record. I might add that the results were especially striking precisely in the most inveterate and seemingly most obstinate cases.

I do not think that there is either any direct or indirect etiological relation between this disease and migraine, especially as it is sometimes accompanied by migrainous exacerbations; yet that which will relieve these will not cure the disease. In the paroxysms I habitually employ antipyrine, phenacetine, the bromohydrate of caffeine, etc., in elevated doses, after which the hemp is continued.

In neuralgia Indian hemp is one of our best remedies, as Russell Reynolds, of London, has demonstrated and of which I am equally convinced. It also acts well in the lightning-like pains of tabes dorsalis; but according to my experience, antipyrine, phenacetine and, above all, exalgine, are still more efficacious. An important group of morbid phenomena which are more or less controllable by cannabis Indica are gastralgias and enteralgias of various origin. This subject having been treated in an important article by Professor Germaine Sée, I shall not dwell long on it. I

shall only recall that, according to this French clinician, the extract of cannabis Indica exercises a special sedative action upon the pneumogastric nerve and gives excellent results in the treatment of gastro-intestinal neuroses independent of disturbances of the chemistry of digestion. In these cases it relieves the painful sensations and restores the appetite. When there is an excess of hydrochloric acid, Professor Sée orders the bicarbonate of soda, in large doses about four hours after each meal, to assist the action of the hemp. My personal experience has confirmed in all particulars the great value of this drug in gastro-intestinal pains. But I should go still further than the Parisian professor and state that I am fully convinced that Indian hemp not only exerts a favorable influence in purely functional disturbances, but also in a large number of gastric and intestinal affections of organic origin.

There is another group of cases where this remedy will render good service; these are cutaneous diseases associated with intense itching. I always attempt to treat itching by local applications, as in the majority of cases it is of local origin and depends upon certain morbid disturbances of the peripheral nerves. But when, as is sometimes observed, local measures fail, I invariably have recourse to cannabis Indica. It is, above all, in senile pruritus that this remedy has been found useful. In these cases I commence with Indian hemp, and if it fail me I then give chloral. In general, it will suffice to administer the hemp in the evening on going to bed, for it is especially during the night that the pruritus is severe. Still there are grave cases where it is necessary to employ the remedy even during the daytime. As it is indispensable, in order to gain control of the itching, to obtain an immediate and rapid effect of the drug, it is preferable to use it in the form of a tincture, as was suggested by Russell Reynolds. Twenty drops of the tincture equal six centigrams of the extract. From five to ten drops may be taken upon a lump of sugar, which dose may be repeated as often as is necessary. Thus the dose of the remedy may be exactly measured.

Since I have been accustomed to prescribe this drug I have rarely had occasion to observe any disagreeable consequences from its administration. I have met with but two or three patients who have refused to continue the remedy, as it gave them vertigo. Only once did I observe grave symptoms of poisoning, and that in a young man of twenty-nine years who had been subject since childhood to attacks of headache. Each paroxysm began with disturbances of vision resembling hemianopsia and was accompanied by confusion of mind and a sensation of weakness; then a pain would set in either in the forehead or vertex and be associated with nausea, but without vomiting. He would feel cold and be obliged to lie down. These seizures were typically migrainous, very violent and setting in every month; during the last few years they had become much more frequent. They were often brought on by a strong light; constipation favored their appearance. The patient was also myopic. In his case I ordered Indian hemp, one pill containing three centigrams of the extract, morning and evening. I also advised him to take phenacetine during the paroxysms (30–60 centigrams) and gave him besides some pills of aloes and myrrh. As there was no amelioration at the end of a month and he having three attacks during this time which were not to be controlled by phenacetine, I increased the dose of the hemp to forty-five milligrams, morning and evening. The next day he wrote me the following: "I took yesterday evening and this morning the pills which you last ordered. The result was unfavorable. On arising this morning I felt very dull. This disappeared after breakfast, probably under the influence of the coffee. But on returning home the sunlight seemed more intense than usual and all the surrounding objects appeared to dance before my eyes. I was as if in a half-unconscious state. A friend who met me found my lips livid and my eyes glassy. At this moment I experienced a sensation as if I were being carried along at the rate of fifty miles an hour. My friend obtained me a glass of water, which enabled me to go about my business. On arriving at my office I felt worse; I could not work and it was with difficulty that I answered questions asked me. My head was very heavy, I felt as if a weight were upon my chest and I noticed a prickling in my limbs. A physician who was called advised me to go home and to sleep off the effects of the drug. I did so. Since this morning I feel as if I were under the influence of a horrible nightmare."

As the pills prepared according to my second prescription were obtained at another source than the first, I advised the patient to return to the use of the first, which he had borne well. A month later I saw my patient. His headache had decreased, but he had undergone another attack of poisoning which he described thus:

"My supply of pills prepared by the first druggist being exhausted, I thought that I might use those made by the second druggist and which had produced such a disagreeable result upon me. I therefore took half of one of these pills in the morning and three-quarters of one in the evening, without noticing any appreciable effect. On the second day following I took half a pill, after which I went into the city according to my usual habit. In crossing London Bridge the sun and daylight seemed to me particularly glaring. At the same time I experienced a singular torpor, and it required decided effort to keep up the conversation with a friend who accompanied me. These symptoms increased rapidly in intensity to such a degree that I could scarcely use my voice and limbs. I tried to conceal my condition from my companion in avoiding his look carefully. I do not know why I did this. My friend left me as soon as we had crossed the bridge. I then retraced my steps, the symptoms becoming aggravated rapidly. I experienced a difficulty in breathing and time seemed infinitely long, an illusion which persisted as long as the poisoning continued. In the train I could not keep quiet. My limbs would jerk and twitch, my temples beat and I was obliged to change my position every minute. On arriving home I went to bed at once, but I could not fall asleep. My wife thought I had gone crazy. I seemed to have grown twenty years older. I was pale, my lips were livid and my eyes haggard. I spoke without ceasing for two whole hours. Then having taken a cup of tea, with bread and butter, I fell asleep for a few moments, to awaken with a start. I then went to sleep again and slept for an hour. After this I felt restored to my usual health, excepting a sensation of weakness. My first poisoning 'spell' had a comatose character, while the second time there were symptoms of excitement."

The painful and disagreeable symptoms which Indian hemp is capable of producing should not force us to renounce its use, for it is a precious remedy. A long experience has convinced me that these accidents are absolutely exceptional. They result from an idiosyncrasy or a variability of the drug in its active constituents. There are individuals who are powerfully influenced by ordinary doses and even weak doses of the extract of cannabis Indica, as has also been observed of other drugs, as the iodide of potash, quinine, etc.

In order to avoid these one should always begin with small doses of the drug and only increase them slowly and when we are certain of tolerance. The patient should also be carefully instructed in this regard, even when obtaining a fresh supply from the same pharmacy. The tincture of cannabis Indica is well adapted to accurate dosage. Therefore this preparation should always be used when a rapid and intense action is desired, as, for example, in the treatment of pruritus. But whenever a slow and continuous action is wished, the extract is undoubtedly the best preparation. To combat certain concomitant symptoms I repeat that it is often necessary to associate the remedy with other drugs, as with aloes if there be constipation, carbolic acid and menthol when there is flatulent dyspepsia, alkalies and bitter tonics in case of catarrh of the stomach. The conclusion of the preceding is that in headaches of a continuous or sub-continuous type, senile pruritus, as well as in the various forms of gastralgia and enteralgia, there is no remedy more active than cannabis Indica, administered in the manner described.

Pepsin Lavements in Dysentery.

Pepsin has been applied to very many of the diseases of the nosology, yet it remained for Dr. Summers, of Waukesha, Wis., to discover that it possesses a most satisfactory therapeutic action in dysentery. He washes out the bowel with a strong solution of pepsin (½ ounce to 6 ounces of warm water) every three hours, which act, he declares, "clears off the mucous surface effectually." He next employs a soothing injection, such as laudanum and starch, as hot as can be borne. He declares that after two or three washings and injections the patient experiences great relief, and healthy action is at once set up, when, if constitutional conditions receive due consideration, rapid healing follows.—*Medical Age.*

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

TREATMENT OF LEUCOPLAKIA.

Dr. S. Rosenberg (*Muenchener Medicinische Wochenschrift*, No. 39, 1894), in an obstinate case of leucoplakia of the tongue which had been treated in vain with the most varied remedies for seven years, caused the disease to disappear in a few days under local applications of a 20 per cent. solution of the iodide of potash.

MORPHINE IN INSUFFICIENT UTERINE CONTRACTIONS.

Dr. Kupffer (*La Semaine Médicale*, No. 55, 1894) has found morphine to be an active remedy in uterine inertia during labor. He employed the following formula:

℞ Muriate morphine..... o | o2 (gr. ⅓).
Cherry laurel water.....20 | o (ʒv).

Twelve drops once or twice during the course of the labor.

He thinks that this remedy acts by diminishing the irritability of the striated muscular tissues, thus producing a relaxation of the perineum while it increases the tonicity of the non-striated fibers, including that of the uterus; whatever be the explanation, he has often observed that small doses of morphine will stimulate the activity of the uterus. One single dose is usually sufficient, but a second may be given if the pains weaken and the head is lodged deeply in the pelvis. At the moment of the expulsion of the head he usually administers a few whiffs of chloroform, thus obtaining greater relaxation of the perineum and a quieting of the pains. He also states that this drug is valuable in hastening tardy contractions when there is uterine hemorrhage.

ERGOT IN THE NIGHT SWEATS OF PHTHISIS.

Dr. Goldenbach (*Hospitals-Tidende*, No. 30, 1894) has employed ergot with success in a number of cases of nocturnal sweating in tuberculosis of the lungs. He administers each evening thirty centigrams (grs. v). In other cases he has employed it subcutaneously with good results. He made use of the following solution:

℞ Extract ergot..... 3 | o (grs. xlv).
Dilute alcohol.....
Glycerine..... } 5 | o ää (ʒ j¼).
Distilled water.....

A syringeful to be injected each evening.

Though he has used this drug for a certain length of time in these cases without disagreeable effects, yet he would not recommend it as absolutely harmless, for a phthisical patient may be poisoned by ergot as well as a healthy person, after a longer or shorter time.

TREATMENT OF MEASLES.

Dr. Sevestre (*La France Médicale*, No. 41, 1894) would have the little patient placed in a large-sized room where there will be no exposure to draught. In summer, during the warm portion of the day, the windows may be left open, while in winter the temperature of the room should be kept even and the room be well ventilated. Do not allow the patient to become uncovered. Keep children in bed ten to fifteen days after the appearance of the eruption, allowing them first to go out twenty to twenty-five days after its appearance. The child's mouth should be washed with an antiseptic solution. Porridges, milk and occasionally an egg will be sufficient as a diet. As soon as desquamation sets in rub the child with borated vaseline and give one or two baths containing borax. Medical treatment is purely symptomatic. For the diarrhœa of the beginning of the disease, lessen the amount of food, apply hot fomentations to the abdomen, give a rectal injection and internally the subnitrate of bismuth with or without opium. In case the cough be very distressing, then prescribe:

℞ Tr. aconite root.....10-20 gtts.
Extr. opium..... o | o2-05 (gr. ⅓-¾).
Syrup ether.....10-20 | o (ʒijss-v).
Mucilaginous mixture 60 | o (ʒij).

To be taken by the teaspoonful.

Hot fomentations to the neck and chest, opiates according to the age of the patient, the bromides or inhalation of steam, are also useful. If the conjunctivitis be very

* In charge of the translator, F. H. Pritchard, A.M., M.D.

intense, use compresses wet with a tepid boric acid solution. In case the coryza be severe, irrigate the nose with a warm solution of salicylic acid (1:1000). For the convulsions and nervous erethism employ lukewarm baths, local application of water of the temperature of the room and the bromides. If the eruption is slow in coming out, look for the cause and administer diffusible stimulants, as the acetate of ammonia, hot infusions, etc.

SUBCUTANEOUS INJECTIONS OF ARSENIC IN CHLORO-ANEMIA.

Dr. F. Pacetti (*La Semaine Médicale*, No. 55, 1894) has obtained excellent results with subcutaneous injections of a solution of arsenic in the treatment of chloro-anemia. He employed a watery solution (0.25 per cent.) of the arseniate of soda, injecting every two days a syringeful. In the course of sixty injections a very decided improvement will have been obtained, when its hypodermic administration may be discontinued and the same drug be continued internally in very small doses to maintain its action. An important point is to combat the chronic constipation from which chlorotics usually suffer, thus giving rise to a more or less auto-intoxication from absorption of harmful substances from the feces. This he treats most successfully by copious daily enemas of water containing a certain quantity of tannic acid. These injections act both as evacuants and as antiseptics. Every morning a full bath, which is gradually cooled, may be taken. With these measures he has obtained a complete cure in cases that were apparently very much advanced.

TREATMENT OF CYSTITIS BY SUBLIMATE INSTILLATIONS.

Dr. Colin (*Medicinische Neuigkeiten*, No. 38, 1894) has tried instillations of solutions of corrosive sublimate in the management of cystitis, as recommended by Guyon. Irrigation of the bladder in case the solution was stronger than 1:4000 was very painful; violent vesical tenesmus would be observed with quite a certainty. On the contrary, instillations of solutions of 1:4000 to 1:5000 were well tolerated and were of service in cases where the nitrate of silver was inactive. Out of thirty-four cases treated thus, twelve were cured, nine greatly improved, nine ameliorated and four uninfluenced. The action was immediate in gonorrhœal as well as in tuberculous cystitis, particularly with regard to the rapid diminution of the pains; even in the most inveterate cases instillations acted favorably upon the number of microbes, the vesical capacity and the pains. The same was true of cystitis of prostatic patients and that of unknown origin. Before instillation the patient should urinate. They are best given at first every two days, later daily, increasing progressively the strength of the solution. The strongest concentrations, 1:1000–1:5000, are only to be used in long-lasting cases. The tuberculous forms require the greatest patience in their treatment; a complete disappearance of the bacilli was not to be brought about. The quantity of fluid injected was five to ten grams into the bladder itself, and ten to fifteen drops into the neck of the bladder and the posterior urethra. No alcohol should be added to the solutions on account of its irritating properties; tartaric acid may, however, be employed.

CHLOROSIS.

Dr. F. W. Warfwinge (*Hygiea*, lvi, heft 6, p. 453, 1894) believes that chlorosis is a distinct and separate disease from anemia. In chlorosis, iron in large doses, preferably Blaud's pills, is indicated and is of the greatest importance, while in simple anemia regulating of the diet is the chief indication, while the use of iron is secondary. The iron in the foods is absorbed to cover the deficiency in the red corpuscles. Chlorosis is essentially an affection of puberty.

NON-OPERATIVE TREATMENT OF UTERINE FIBROMATA.

Prof. Lutaud (*Journal de Médecine de Paris*, July, 1894) advises wearing an abdominal bandage in case the woman suffer from symptoms of compression from the increase in size of the tumor. Massage will also relieve the secondary symptoms, meteorism, constipation and cystitis, as well as help to reduce the size of the abdomen. If there be severe metrorrhagia introduction of a laminaria or a sponge tent will assist in controlling hemorrhage. The galvanic current is also

of service, the positive pole in the uterus and the negative applied to the abdomen. Hydrastine has been employed by him with success for several years, not only in controlling the hemorrhages but also in reducing the accompanying uterine hypertrophy which is observed with these tumors. He injects the drug hypodermically, using the following formula:

℞ Muriate hydrastine..... 0 | 50 (grs. vijss).
Distilled water..... 10 | 0 (3ijss).
One syringeful to be injected each day.

In case they are not well borne he administers the tincture of hydrastis canadensis as follows:

℞ Tr. hydrastis canad..... 4 | 0 (3j).
Syrup opium..... 30 | 0 (3j).
Distilled water..... 150 | 0 (3iv. 3vj).
A soupspoonful three times a day.

Ergotine is the remedy usually employed and deserves the confidence of the practitioner. It is best administered hypodermically. Whenever there are heart complications with great vascular distention he associates with it digitalis and the iodide of potash as follows:

℞ Syrup digitalis..... 60 | 0 (3ij).
Iodide potash..... 10 | 0 (3ijss).
Syrup orange peel..... 120 | 0 (3iv).
Ergotine..... 2 | 0 (grs. xxx).
A soupspoonful morning and evening.

Ergot may also be given by the mouth where it is objected to subcutaneously.

Constipation is an almost constant symptom in cases where the tumor is voluminous and is accompanied with pain and tympanites. These symptoms are due both to adhesions and to false membranes, so that both laxatives and opiates are to be used at times, as indicated. A highly nutritious diet should be ordered to prevent dilatation of the stomach and intestines. Magnesia associated with salol will combat the constipation and prevent intestinal infection:

℞ Calcined magnesia.....15 | 0 (3iv).
Salol..... | 50 (grs. vijss).
Sufficient for fifteen powders. One at the beginning of each meal.

When there are vomiting and obstruction of the biliary passages he prefers calomel, which may be given with opium, to avoid colicky pains. He advises the following formula:

℞ Calomel..... 1 | 0 (grs. xv).
Extr. opium..... 0 | 05 (gr. j).
Sufficient for ten pills or powders. One each morning and evening.

IODINE GIVEN WITHOUT DISAGREEABLE SYMPTOMS

Dr. Hardaway (*La Semaine Médicale*, No. 54, 1894) advises the following mixture as free from the ordinary disagreeable after-effects of the iodic preparations:

℞ Iodide potash.....15-30 | 0 (3iv-3j).
Citrate iron and ammonia. } 8 | 0 āā (3ij).
Tr. nux vomica..... }
Water..... 45 | 0 (3jss.).
Compound tr. cinchona.....60 | 0 (3ij).
A teaspoonful after each meal.

SOME FATAL AFTER-EFFECTS OF CHLOROFORM IN CHILDREN.

Dr. L. G. Guthrie (*Centralblatt f. d. Medicinischen Wissenschaften*, No. 37, 1894) calls attention to a severe and nearly always fatal after-effect of chloroform in children, with the following course. Immediately or some hours after the operation vomiting occurs, the child becomes restless, delirious and cries constantly, while the whole appearance is that of one suffering from mania. The child's face is reddened, rarely pale, the eyes dry and the pupils dilated. After some time an apathic condition follows, while consciousness returns during the remission. Then follows wild delirium and thus it is continued until, in the course of several hours or a few days, the child succumbs. The writer has observed ten such cases, of which only one recovered. In all these there was violent and continuous vomiting; the vomited matter contained no blood, but always bile. The temperature was subnormal, rarely elevated. Death takes place with symptoms of increasing collapse. He ascribed the condition to a fatty infiltration of a previously fatty liver. In fatty liver in children he therefore thinks chloroform contraindicated. Clinically, however, this is difficult to diagnose.

Pilocarpine in Urticaria.

Dr. R. Abrams, of New York (*Med. Record*), claims excellent results from the use of this drug in the treatment of both acute and chronic urticaria. Adults should get the drug hypodermically in doses of one-sixth to one-half a grain. Children of one year should get it by the mouth in doses of one-twentieth to one-eighth of a grain every evening at bed-time. For children two or three years old the dose is one-fifteenth to one-sixth. The writer claims that pilocarpine is almost a specific. By administering the drug with care and increasing the dose gradually no untoward effects need be looked for. It is a good plan to stay with the patient for twenty minutes after giving the drug.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, NOVEMBER 3, 1894.

EDITORIAL.

EXPERIMENTAL TYPHOID FEVER.

Sanarelli (*Ann. de l'Institut Pasteur*, April, 1894) gives an account of an exceedingly interesting series of experiments in the production of a disease by typhoid toxin which resembles closely that produced by the bacteria themselves. The toxin was prepared by inoculating flasks of the culture fluid with virulent typhoid bacilli, and allowing them to stand for about a month at a temperature of 37° C. They were then sterilized and kept at the ordinary temperature for about eight months, at the end of which time they were hermetically closed and allowed to macerate for several days at 60° C. The liquid in the flasks formed two layers, the upper being perfectly clear, which was carefully removed. The toxic and pathogenic effect of this fluid was tested on rabbits, mice, guinea-pigs and a monkey. The summary of the results obtained in reference to typhoid is as follows:

1. Eberth's bacillus, having penetrated the organism, produces a toxin which acts on the nervous system and brings about death by collapse.

2. In addition to this toxic effect, this toxin acts peculiarly on the mucous membranes, especially of the intestine, and thus brings about the familiar lesions.

3. All of the anatomical changes produced by the toxin, and independently of the virus, are accompanied by symptoms presenting very close analogies with those of human typhoid.

4. In experimental, as in human typhoid, Eberth's bacillus is not found in the intestinal contents; this fact militates against the idea that the disease is a process infectious in origin localized in the intestine.

5. The absence of the specific organism from the contents of the intestine is explained in two ways: (*a*) Because typhoid fever is an infection of the lymphatic system only; (*b*) because directly the poison begins to act on the intestinal walls *B. coli* becomes pathogenic, and increases so enormously as to obliterate other forms.

6. Given the grave toxic anatomical changes of the intestinal mucous membrane, the *B. coli* constitutes the first

cause of the secondary infections and local izations so frequent in the disease.

7. If the animal is partially vaccinated the *B. coli* in the intestine produces only local effects.

8. Animals vaccinated against Eberth's bacillus are also vaccinated against *B. coli*.

Dr. William Goodell.

Dr. William Goodell, the eminent gynæcologist, who had been in failing health for the last two years, died at his residence, 1418 Spruce Street, on Saturday morning, aged 65 years.

Dr. Goodell was the son of the Rev. Wm. Goodell, D.D., of Holden, Mass., and was born on the island of Malta while his parents were journeying to Turkey, where his father was engaged in missionary work.

In 1849 he entered Williams College, Massachusetts. Graduating three years later, he came to Philadelphia and continued his studies at the Jefferson Medical College, and received his diploma in 1854. The same year Dr. Goodell rejoined his father in Constantinople, and there entered upon the practice of his profession. In 1857 he married, at Smyrna, Asia Minor, Caroline, daughter of the late Judge Thomas S. Bell, of West Chester, Pa., who survives him. In 1861 he returned to America on account of the unsettled condition of political affairs in Turkey, and, locating in West Chester, there commenced practicing medicine in this country.

Dr. Goodell made a specialty of obstetrics and diseases of women, on the subject of which he was a prolific contributor to the medical journals, and was also the author of "Lessons in Gynæcology."

In 1865, on his appointment as Physician in Charge of the Preston Retreat, at Twentieth and Hamilton Streets, he came to reside permanently in this city, and continued to hold this appointment until 1887.

In 1870 he was appointed Lecturer on Obstetrics and Diseases of Women of the University of Pennsylvania, and in 1874 Clinical Professor of the University of the Diseases of Women and Children. He was also Honorary Professor of Gynæcology of the University, a member of the National, State and County Medical Associations, of the College of Physicians, of the American Philosophical and American Pathological Societies, and a correspondent of the Boston Gynæcological Society, of the London Obstetrical Society and of the Imperial Medical Society of Constantinople.

Congenital Constipation.

F. Huber reported the case of a boy, five weeks of age, who since birth had been troubled with constipation and colic. When first seen by the author he was suffering great pain, straining and kicking. The abdomen was swollen and tympanic and the child had been vomiting for two days. The temperature was 102°. By process of elimination a diagnosis of acute intestinal obstruction since birth was arrived at. It was due to an impaction of fæces in the reduplication of the sigmoid flexure of the colon, a condition frequently misunderstood or entirely overlooked. While in many cases it was a very trivial matter, still it was not uncommon for it to lead to serious illness and even to seriously jeopardize life. In infancy the descending portion of the colon was disproportionately long, and by being crowded down into the narrow pelvis it formed a number of curvatures instead of one sigmoid flexure. The treatment consisted in giving high rectal injections until the proper relation had been established between the colon and the sigmoid flexure. It was, of course, often necessary to continue the treatment for years.—*Boston Med. and Surg. Jour.*

Treatment of Laryngeal Phthisis.

Dr. Hajek presented a patient with laryngeal tuberculosis upon whom he had tried a new treatment. The infiltration of the epiglottis was so great that the man could no longer swallow. Dr. Hajek removed the entire epiglottis by means of a galvano-caustic loop, and treated the wound with lactic acid. Four weeks later the patient was able to swallow with ease. Since then he had curetted one of the vocal cords which was ulcerated. This was also dressed with lactic acid and healed rapidly. It is now one year since the epiglottis was extirpated, and the cure is maintained. The patient has increased in weight 19 kilogrammes (38 pounds), proving that his general condition is better. Dr. Hajek stated that he had already extirpated the epiglottis of three patients.

ABSTRACTS.

PEPTONES.

It is commonly supposed that peptones must be the products of the action of pepsin on proteid and albuminoid substanees. As a matter of fact, however, *true* peptones result from the fermentative activity of pancreatin. As will be seen by the pharmacopœial tests, under the respective headings, pepsin is active only in acid solution, pancreatin only in alkaline solution. There is one ferment, however, which is active in neutral solution, and this is papain, the so-called vegetable pepsin. A word as to the production of these various ferments. Pepsin, as is well known, is prepared by two general methods, producing "precipitated" and "soluble" pepsin, respectively. The former is prepared by exhausting the mucous membrane of the pig's stomach with water containing hydrochloric acid and precipitating with sodium chloride; the latter by macerating the mucous membrane in acidulated water and evaporating the resulting solution nearly to dryness, redissolving, precipitating the peptones formed by means of appropriate agents, evaporating and scaling. Pancreatin, or "trypsin," is mostly obtained by extraction of the pancreas with glycerin and precipitating with alcohol. Papain is obtained by expressing the fruit of carica papaya, diluting the resulting milky juice with water, allowing the resinous constituents to precipitate, filtering, and precipitating by means of alcohol.

"Peptones" are divided into the following four classes:

1. Pepsin-peptones. These are obtained by allowing gastric juice, or pepsin in acid solution, to act upon albuminous substances; these may be egg-albumen or the albuminoids in meat. When the previously coagulated albumen is entirely liquefied or rendered diffusible by the action of the pepsin, the product is called albumose, which is considered to be nothing more than a hydration product of albumen. Its advantages over albumen are its greater solubility, easier diffusibility and its non-coagulation by heat. The majority of true pepsin-"peptones" are made, however, by allowing pepsin in acid solution or gastric juice to act on fresh beef previously freed from fat and sinews for 12 hours at a temperature of 150° C. (22° F.). After cooling the liquid is filtered through a moist filter to retain all fat, tested with nitric acid for unconverted albumen, neutralized with sodium carbonate and concentrated in vacuo or on the water-bath either to syrupy consistence or to dryness.

2. Pancreas-peptones. These are the *true* peptones. They may be obtained by acting on albuminous substances with pancreatin in alkaline solution (sodium carbonate or calcium hydrate), otherwise proceeding precisely as stated under pepsin-peptones. The action of pancreatin, or "trypsin," is accompanied by deeper-reaching changes than that of pepsin, such products as leucin, tyrosin, etc., being formed. The pancreatin-peptones possess a far more disagreeable taste than the pepsin-peptones or albumoses and are also inferior in keeping-power.

3. Peptones from vegetable pepsin. These are now produced in not inconsiderable quantities by allowing papain to act on meat. The juice of the agave or century-plant, as well as that of the pineapple and American pawpaw, also comes within the realm of vegetable pepsin. These peptones, however, have long been regarded not as true peptones but as identical with the next and last group.

4. "Meat solutions," obtained by superheated steam. Under this heading we may also include those solutions which are obtained by the action of boiling water+hydrochloric acid on meat. To prepare such peptones meat, previously freed from sinews and fat and finely comminuted, is placed into cold water contained in a vessel fitted with a nearly air-tight cover and a false bottom to prevent the meat from burning. The water may contain 2 per cent. of hydrochloric acid or not; but the addition of the acid will shorten the process. After boiling for 10 to 15 hours, removing from the fire, rubbing in a mortar to an emulsion-like consistence,

and boiling for another 15 to 20 hours, the resulting liquid will contain true albumoses and peptones, although not consisting entirely of such, since not all of the albumen is converted by the heat. Here is a field that offers good returns in more senses than one to the pharmacist. In view of the fact that the market is flooded with so many "peptones" and "solutions of peptones," some of which depend more upon the wine and coca than upon the presence of any real peptone, and that they often produce imaginary rather than real results, the pharmacist should prepare his own peptones and introduce them to the notice of the physicians with whom he comes in contact, explaining to them that peptones are exceedingly prone to decomposition, and that therefore they cannot reasonably be expected to keep for any considerable time.

To show the physician how he may in from 4 to 12 hours' time, by digesting 1,000 grams of prime beef with about 10 grams of pepsin, 40 cubic centimeters of hydrochloric acid, and sufficient water, produce about 250 grams of peptone, representing in a soluble and predigested form the 1,000 grams of beef, should thoroughly convince him that reliable peptones can be furnished by the pharmacists. Care should always be taken, however, to neutralize the free acid by means of sodium carbonate.

By a little experimenting the pharmacist may for himself find out the best methods and manipulations for producing peptones, *true* peptones, which will give good results, and which are, in addition, more profitable to sell than the proprietary articles of commerce.

In conclusion it may be said that the true peptones, or those produced by pancreatin, seem to possess not any more nutritive value than the albumoses, or the "peptones" produced by pepsin. Either of these possesses a very disagreeable taste, and, as before mentioned, will not keep very long. The taste of the solution must therefore be corrected, either by salt and pepper or, preferably, by a quantity of beef extract. It may sometimes be indicated that the so-called meat alkaloids or bases (syntonin, etc.), also the salts (potassium phosphate, etc.), should be removed. In that case the meat to be acted on must be extracted with boiling water previous to subjecting it to the action of the ferment. The solution may be evaporated and again added to the peptones, if necessary, in part or in whole. As peptones are soluble in wine, syrup or hot water they can be made palatable as well as nutritious, and also—remunerative.—*Western Druggist.*

PATHOLOGY OF PNEUMONIA.

Dr. F. O. Broady, in *Sanative Medicine*, says: Whatever the cause may be, the disease begins with a recession of the blood from the surface, or the capillaries of the skin, and a predisposition of an unusually large blood mass to accumulate in the lung capillaries. Any sudden chilling of the surface with a corresponding deficiency of tension or tone of the lung capillaries will produce this condition, on the principle that a fluid will find the point of least resistance. An increase of blood in any part of the body will lead to an inflammatory condition there, in which expression the idea of softening of normal tissue is involved, and this softening takes place very rapidly; in fact it begins at once, whether the walls of the lung capillaries are weaker than usual either on account of the youth of the patient or because of the poisons, as alcohol previously taken, or whether they are not previously weakened. In either case it will not take long before this inflammatory softening causes the vessel walls to give way at some point, slightly at first, perhaps not more than enough to permit serum to filter through without the red corpuscles, but as the process goes on, even these corpuscles find openings large enough to escape, and the air-cell rapidly fills up with exuded blood material. We now have the stage of red hepatization. The effusion of all this matter is a most fortunate thing, however, and is perhaps the only chance the patient has for his life, for the air-cells are not only filled, but also *distended* by the escaping blood. The result of this distention is to press on the blood-vessels in that immediate neighborhood, and this outside pressure furnishes the tone to the vessel walls that was lacking, and the heart can

no longer send such an excessive amount of blood to parts that now are not so atonic, but must find room for it in another region of the body. The pressure from without on the blood-vessels also, of course, has a tendency to check the escape of blood-elements. If the air-cells were only filled and not distended, we would have a condition in which the exuded blood-elements would have a regular supply of food furnished through the breaks in the vessel walls, and through this regularity of food supply would increase and then form new tissue: this to the utter destruction of any hope of ever getting the air-cell clear again from foreign matter in order that it may perform the function for which it was intended. This condition, or one very similar, does actually exist in interstitial or chronic pneumonia. The distention, then, of the air-cells by the exuded blood-elements is fortunately great, and it is also sudden, which is also fortunate. This rapid and great distention leads to a rapid and considerable shutting off of the previously existing food supply (found in the blood) to the tissue germs already found in the air-cell, and here, as everywhere else, a considerable and rapid limitation of the food supply to a part leads to fatty and other disorganizing degenerations.

We now have arrived at the stage of "gray hepatization." When a cell undergoes fatty degeneration it increases in size, and, hence, this results in still greater distention of the air-cells, which leads to a still greater limitation of the food supply to the part, and which naturally produces a more sure and rapid fatty degeneration. It is necessary to have this fatty change in the exuded material, because this is the only state in which it can be consumed by the white blood corpuscles which swarm wherever an injury has taken place, consume the *débris* and reënter the circulation when the destruction has been repaired. The organism has to depend on these corpuscles to repair the pneumonic injury and carry off the exuded blood and tissue elements, for these cannot be coughed up: nothing can be coughed up behind which a considerable quantity of air cannot get.

CERVICAL GANGLION OF THE UTERUS.

BYRON ROBINSON, M.D.

It would astonish any student to know how little has been published in regard to the nervous system of the female genitals which is of an original character. The reason for this is at once apparent when one pursues the study for several years. Of course the simplest and easiest way is to dissect the genitals of man and animals. But few do that. And, besides, to dissect with value and discrimination requires time, experience and patience. The best way is to secure an infant cadaver and drop it in alcohol for several weeks, and for comparison secure some six to eight weeks' fœtal pigs from the slaughter-house and treat them likewise.

To get at the parts most readily, open the infant's abdomen and take away the hip-bone. Unjoint it at the sacro-iliac joint, then cut it away at the tip of the ischial spine, and then saw through the pubic rami at the center of the obturator foramen. The field is now clear. Next, observe the course of the hypogastric plexus just beneath the peritoneum at the promontory of the sacrum. It will show itself like white threads shining through the peritoneum. The white lines are the hypogastric plexus and should be carefully followed by a sharp-pointed scissors as far as the region of the cervix. Now, with gentle care, clear away the various tissues from the roots of the first, second, third and fourth sacral nerves. It will by this time be clear to the sight that the lower end of the hypogastric plexus and the branches from the sacral nerves (especially the third and fourth) converge near the cervix into a mass of white tissue. This mass of whitish-gray tissue is the ganglion of the cervix uteri. So far as I can ascertain, this ganglion was first described by a physician named Walter. The existence of the ganglion has been denied by Snowbeck, of the English, and by Kilian, of the French. The defenders of the ganglion are chiefly Lee (1842) and Frankenhausen (1867). The names of

those who have worked at this ganglion are very few even to this day. The only worker on this ganglion that I know of in the last generation is Dr. Jastrobef, of St. Petersburg, in the clinic of Professor Slavjansky. Dr. Jastrobef used thirty bodies to secure anatomical and pathological knowledge. I have been working at the nervous system of the female genitals for some five years, and I did not become aware of Dr. Jastrobef's labors until August, 1894. Nearly every worker in this subject comes to essentially the same conclusions, but some little manifestations arise which induce said observer to think every other investigator overlooked. Lee and Frankenhauser showed with anatomical positiveness the largeness and solidity of the cervical ganglion, while Snowbeck and Kilian tried to belittle its size and even its existence. Jastrobef's short account simply sides with the idea that the cervical ganglion is a mere plexus of nerves.

After careful dissecting (man and animals) I must say that the cervical ganglion is a veritable ganglion, just as the superior cervical ganglion is. The cervical ganglion is a real ganglion. It is true it varies in shape and size, as all sympathetic ganglia do, but it is constant and real. I shall carry on this investigation for the next few years in man and animals and prove its constancy. The last cadaver which I dissected for the purpose of identifying the ganglia for study was that of a woman about seventy years old. The ganglion was fully three-fourths of an inch long and over one-fourth of an inch wide. It was a thick, hard, irregularly shaped mass of nerve-tissue receiving the hypogastric plexuses and the branches of the sacral nerves and sending out many small nerves to the uterus, bladder and rectum. The ganglion in this special case received all the branches of the sacral nerves before they entered the uterus and all the nerves of the hypogastric plexus, except two or three, before they were sent to the uterus. It appears, then, that the cervical ganglion is the distributor of nerves to the uterus. It is no doubt the ganglion of the uterus. Its business is to control the uterus. Leashes of nerves start out of this ganglia to the uterus, bladder and vagina. The vagina was, next to the uterus, the favored organ for numerous strands. The ganglia lie near the cervix, one on each side. In the above case the right cervical ganglion was much more solid and compact than the left. More than a dozen branches could be counted going to the uterus, to the vagina and to the rectum, in the order of abundance. In this case of a woman seventy years of age the ganglion was perfect and distinct, as it is in an infant cadaver. The wonderfully intimate nervous connection of the uterus to both rectum and bladder should be a lesson to the gynecologist. The uterus, rectum and bladder are richly supplied by many strands from the same great trunk (hypogastric plexus). It is almost impossible to irritate one organ without the other two being brought directly into the disturbed field.

During the last five years I have had many subjects (man and animals) to study the sympathetic nervous system, and one fact has time and time again impressed me. This fact is the widespread and profoundly intimate nervous connection of the kidney and genitals. So far as the nerve connection is concerned the organs should be written genito-urinary, with a distinct hyphen. The explanation arises in embryology, where both genital and urinary organs arise from the same source —the Wolfian body. I wish to give credit for this same idea to Dr. Frankenhauser, whose work I was able to secure only a few months ago, as it is out of print. A glance at a well-dissected sympathetic nervous system lying *in situ* would enable a physician to cast aside forever an error long propagated in obstetrics, and to my own knowledge taught even to this day from obstetric chairs. It concerns pressure over the sacral promontory to stop post-partum hemorrhage. It is taught that pressure compresses the aorta so that the blood is checked from going to the uterus. A few actual trials in obstructing the aorta by pressure will soon dispel the delusion. The facts in the case are that the irritation of the hypogastric plexus (in attempting to compress the aorta) induces the uterus to contract. The more pressure and vigorous irritation applied to the sacral promontory the more vigorous and certain will be the uterine contractions, so that the explanation of how post-partum hemorrhage is checked by compressing the aorta is certainly wrong. The mechanism is accomplished by the irritation of th hypogastric plexus. So far I have no had the opportunity of dissecting a preg

nant uterus, to determine whether the cervical ganglia enlarge, but both Lee and Frankenhauser say they do. It is probable, however, that John Hunter is correct in his suggestion that it is the connective tissue, and not the nerves themselves, which enlarges in pregnancy. Almost every investigator of the uterine nerves has come to the opinion that it is the infant cadaver which serves the best purpose. The nervous system of the infant is disproportionately large and is plain to the eye, and it can easily be separated from the delicate connective tissue. The cervical ganglia are very plain in the infant. Two to four nerve-branches pass along with the ovarian vein and artery to the ovaries. At the junction of the tube and uterus (*i.e.*, at the origin of the round ligament) the ovarian and uterine nerves join—anastomose. The cervical ganglion, of course, shrinks after the menopause, but its shrinkage must be limited, as many of its branches supply the rectum and bladder, organs which persist in further use. Yet it appears to me that the rectum and bladder in old female cadavers are considerably atrophied as well as the uterus.

Jastrobef in his short article notes that in disease of the genitals on one side the ganglion of the same side is affected. He reports two cases where the ganglion and the genitals of the same side were both diseased. As a considerable portion of the cervical ganglia rests on the vagina, even total extirpation of the uterus would include but a very small part of the ganglia, for the cervical ganglia are situated too low down to be included in the extirpated uterus. These few remarks may call attention to the cervical ganglion of the uterus, its limited literature, the varied opinions as to its existence, shape and size, as well as the slight records of its functions and pathology.—*Med. Rec.*

THE INHALATION OF OXYGEN IN OPIUM-POISONING.

The usefulness of potassium permanganate as an antidote in the treatment of opium-poisoning may, in view of the evidence presented, be admitted. Upon what this antagonistic action depends has, however, not yet been demonstrated, though it is reasonable to assume that the oxidizing quality of the potassium salt plays a prominent role in this connection. This supposition would, in some measure at least, seem to be supported by the fact that the permanganate has also proved useful in the treatment of phosphorus-poisoning, cyanid-poisoning, and snake-bite. Further confirmation of this view appears to be afforded by the recent experience of Merry (*Lancet*, No. 3,692, p. 1372), who reports a desperate case of opium-poisoning in which inhalations of oxygen seemed to act as the determining factor in bringing about recovery. The victim, a male, thirty-two years old, had, three hours before coming under observation, taken of a preparation of variable composition an amount supposed to represent eight grains of morphine. The man was unconscious, cyanotic, and breathing stertorously about fifteen times per minute. The corneal reflex was abolished, and the pupils were small and inactive. Flagellation, cold affusion, the use of the interrupted current, the vapor of strong ammonia, the subcutaneous injections of ether failed to bring about reaction. The respirations were labored and had fallen to eight per minute, and the pulse had become almost imperceptible. The cyanosis suggested the use of inhalations of oxygen, and these were forthwith instituted, pure, undiluted gas being employed. In the course of twenty minutes the face had regained its normal color, the respirations were fuller, easier, and more frequent, and the pulse had become perceptible and regular. The patient was still stupid, although there was a slight response to corneal irritation. After an interval of half an hour the inhalation of the gas was resumed, with further marked benefit. Consciousness returned, and after the repetition twice of the inhalations after intervals of three-quarters of an hour, the point of danger seemed to have been passed. The man remained drowsy during the day, but did not relapse into stupor. He made a perfect recovery. The suggestiveness of this experience is entirely obvious, and the safety and innocuousness of the method must surely commend it to favorable consideration and intelligent trial in suitable cases.—*Medical News.*

PRIMITIVE MAN.

From a geological point of view the Human Period comes so late in the history of the building up of the crust of the earth, so late in the long succession of animal life, that its date must be referred to the rocks now in process of formation. One of the few things, indeed, which carries the early part of the Human Period back beyond our present associations is that there lived in what we are wont to call the beginning, coeval with man, many animals which are now extinct. We may fairly assume that the relics of primeval man which it has been the good fortune of the geologist to discover did not belong to the lowest type of humanity. Primeval man in the true meaning of the term must have been a creature of considerably lower cranial development than any hitherto discovered, for some skulls are about equal to, while others show a considerably higher brain capacity than, many of the lowest modern savages. The fact that there are now living in the world creatures of our own race whose cranial capacity and conformation places them on a level with, or lower than, the earliest discovered man, is of great interest; for if we assume—and this may be done without great error—that the lowest of these ancient skulls is a fair representative of the development of the age in which its possessor lived, then we arrive at the mental capabilities of the inhabitants of Europe in those days by observing people of similar development in the present day.

Prior to the commencement of the last Glacial Period there is no proof of the existence of man. The climate of Northern Europe could not, however, have been the cause of his non-appearance; for if we may judge from the remains of the flora underlying the glacial drift, and immediately above the chalk near Cromer, it must have been congenial to a form of vegetation similar to that of the present day. Strange, indeed, does it appear that among these relics of the age immediately preceding the last Glacial Period we have no trace of the existence of man; but whether he had not then come into existence, or was in those days one of the rarer species of mammalia, cannot be positively affirmed. Certain it is, however, that in the first discovered specimens man had attained a comparatively high state of development, and that there was nothing in the climate of the period immediately preceding the last time when Northern Europe was enveloped in sheets of ice which could prevent his living comfortably on our shores, for we know that the geographical distribution of our race is infinitely greater than that of plants, mollusks, and the mammals immediately below us in organization. Those who hold the doctrine of development in any form cannot suppose that man was introduced on to the earth at that stage in which we first find his remains. The search must be made considerably earlier if primeval man is to be discovered, not necessarily in Northern Europe, or even the northern hemisphere, but more probably in those strata which in a more temperate climate were in course of formation during the last Glacial Period in our country.

During that great age of ice, Northern Europe was quite as uninhabitable as the middle of Greenland is at the present day. So great was the accumulation of ice and snow that at times it buried the highest mountains in England and Scotland to a depth of two or three hundred feet, completely filling the bed of the North Sea, and thus joining the British Isles to Scandinavia, Germany and France. Westward, the vast ice-sea crept away far out into the Atlantic, for miles grinding along the bottom of the ocean, till the water became sufficiently deep to enable it to float. The terminals, like those of existing ice-sheets in the far North and in the glaciated regions of the South, formed immense cliffs, standing hundreds of feet in height, from which every now and again massive icebergs would break away, and, sailing southward, would gradually melt as they reached the warmer air and water between the fortieth parallel and the Tropic of Cancer. That this country, as well as the rest of Northern Europe, has been enveloped in a vast ice-sheet is so well established a fact that it hardly seems necessary to recall evidence on the subject. It may readily be conceived that when the last Glacial Period came on, in place of the mild climate which preceded it, it would change the aspect of the country as completely in the animal as in the vege-

table world. But after this age of intense cold had last for thousands of years, the winters again became shorter, and the summer sun reclaimed first a coast line, and, having thus obtained a more congenial element on which to expend his warmth, drove back the ice-sheets inch by inch into the fastnesses of the hills. Ocean currents depressed into the southern hemisphere now poured tepid waters into the northern seas, which rapidly dispelled the sheets of floating ice, and, as they played upon the shores of Europe, aided to a great extent the other causes which have brought about the climate we now enjoy.—*Public Opinion.*

THE BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA.

Since the publication in the *British Medical Journal* of August 18th of the important communication by Dr. Hermann Biggs regarding the bacteriological diagnosis of diphtheria, the general press has repeatedly referred to the subject. It must not, however, be imagined that London has been absolutely supine in the matter. The report of the medical officer to the Local Government Board for 1891–92 contained a report by Dr. Klein showing that by bacteriological investigation the cases in which scarlet fever was complicated with membranous sore throat could be divided into two classes, one of which was truly diphtheritic and the other was not, with this general result, confirming what had been discovered before, that membrane occurring in the early days of scarlet fever was not diphtherial, whereas that which came on in the later stages and in convalescence was true diphtheria. On March 15th of this year a paper was read before the Medical Society by Dr. Wethered, on the "Diagnosis of Diphtheria by Bacteriological Cultures," giving details of the process and its results. The medical officers of the hospitals of the Asylums Board have endeavored to differentiate the mass of membranous throats coming before them into the true and the false types. In the report of the Statistical Committee for 1893 mention is made of certain bacteriological investigations having been undertaken. Some of the results were reported to the Clinical Society by Drs. Washbourn and Goodall on January 12th, and more lately the method has been largely used at the South-Eastern Hospital by Dr. Thomson. No doubt the pathologists at the various general hospitals have also carried out investigations on the same lines but on a smaller scale, and the Clinical Research Association, the institution of which we noticed last week, is ready, for a small fee, to examine membrane forwarded to it and report by telegram. What, however, has not been done, we believe anywhere except New York, is to create a municipal organization by which, as part of the ordinary sanitary machinery of the health department, the bacteriological diagnosis of diphtheria shall be put at the disposal of the profession. The organization there is so complete and its efficiency is so highly spoken of by Dr. Hermann Biggs that we cannot but hope that some county council, preferably that of London, will take the matter up in the same spirit. The culture tubes would be stored at numerous depots, probably the vestry offices. All that the doctors would have to do would be to obtain the tube, inoculate it by means of a sterilized swab supplied in a separate tube along with the culture medium, replace the cotton plug, and return the tube to the depot. At a certain hour every afternoon these tubes would be collected from all the stations, and taken to the central laboratory, where by noon the next day the diagnosis would be ready to be dispatched by letter or telegram, according to the urgency of the case. The importance of the matter is greatly increased by the assertion of Dr. Biggs, in which he merely confirms the observations of Prudden and Baginsky, that a very large number of cases of membranous sore throat are not due to the bacillus of diphtheria, but merely to ordinary cocci, and that the mortality of such cases is practically *nil*. In New York they do not accept these non-bacillary cases at the hospitals, and on the other hand they do not discharge cases of true diphtheria until bacilli cease to be found, sometimes not for several weeks. When the tubes are prepared wholesale the expense is said not to be great, and probably as an experiment the bacteriological work would be undertaken by an existing laboratory.

EPIDEMIC MUSCULAR RHEUMATISM.

Dr. Isaac Newton (Tonbridge, Kent) sends the following note on an affection which has appeared in Kent recently:

I have seen a comparatively large number of cases (43) of acute muscular rheumatism during the last five weeks, all presenting an extraordinary similarity, so much so that I was able confidently to predict the exact course that any individual case would take. I have seen no record or description of anything of this nature occurring in such an epidemic form. It comes on suddenly, and is characterized by pain, increasing in intensity for a few hours until it reaches its maximum, situated in and affecting the abdominal and lower intercostal muscles, rendering breathing painful, short and rapid, not infrequently also affecting the muscles of the back, especially in the lumbar and upper sacral regions. It is accompanied by a rise of temperature, ranging from 100° F. to 104° F., according to the severity of the attack, with its usual concomitant effects of headache, injected conjunctivæ and furred tongue. The pulse remains comparatively slow, 80 to 90 beats a minute, occasionally 100. The patient perspires more or less profusely, giving off the peculiar acid odor of a rheumatic affection. There is no vomiting, feeling of nausea or other gastro-intestinal disturbance. If treated with such drugs as quinine, acetate of ammonia or sweet spirits of niter, or if it be left untreated, it runs a course of about three or four days, the pain and fever gradually abating on the second or third day. In two cases it was accompanied on the second day by acute endocarditis

I look upon it as entirely distinct from influenza, which it resembles, and as having a rheumatic origin, for the following reasons:

1. Although I have seen such a considerable number of cases during the last few weeks, I have not had a single case of any of the recognized varieties of influenza.

2. It is not followed by any of the marked depression or weakness so characteristic of influenza.

3. It is peculiarly amenable to treatment: 10-grain doses of salicylate of soda together with 15 grains of bicarbonate of potash administered every four hours invariably brought down the temperature in from six to twelve hours. This combination of drugs has, so far as I know, no such specific effect in influenza.

4. If infectious, it is very slightly so; as, of all the cases observed, in only one instance has more than one member of the same household been affected. (A servant had it, then in exactly seven days the wife and seven days later the husband were attacked.) I conclude that it is not infectious, a strong contrast to influenza.

5. There has been no complication or affection of either lungs, air-passages or nasal cavity concurrent with or as a sequel to it in any single case.

6. Lastly, and not least, the heart complication points strongly to a rheumatic origin.

Example.—G. J., aged 32, was taken with acute pains in the abdomen and in the lower intercostal region on the afternoon of August 4th. That evening I found him in bed, with difficulty of breathing owing to the affection of the lower intercostal muscles on both sides; pulse 92; temperature 103.4° F. He was perspiring profusely, the acid odor of the perspiration being well marked. The heart-sounds were normal, and nothing abnormal was to be found in the lungs. I prescribed the following:

℞

Sodii salicylatis	5j.
Potassii bicarbonatis	5j.
Liquor opii sedativi	5ss.
Spiriti chloroformi	5jss.
Aquam ad	5viij.

One-sixth part every four hours.

I saw him twelve hours later, and found that all pain had ceased after taking two doses; the temperature was 98.4° F. The patient was practically well. He got up that afternoon, and I put him upon an alkaline and gentian tonic. On August 6th he returned to work; he has since felt no return of the pain, and has been perfectly well. This tallies exactly with and might be an exact description of all the other cases so treated.

The cases above mentioned of heart complication occurred before I had discovered the specific effect produced by salicylate of soda and bicarbonate of potash. There was no valvular disease in them previous to the attack. Only a few weeks before I had both these patients

under notice; the condition of their hearts was noted accurately, and there was no trace of any cardiac murmur or trouble to be made out then. I attribute these attacks to the exceedingly wet summer that we have experienced this year. This district lies especially low in the valley of the Medway.—*British Med. Jour.*

HEMORRHOIDS.

In complaints of rectal troubles, make diagnosis before you prescribe. If piles, discover what kind, whether external or internal, bleeding or not bleeding, protruding or not protruding. External, inflamed piles require, in a degree, the same treatment as internal; yet the external require an astringent which the internal cannot bear. Bleeding piles need different treatment from those that do not bleed, and protruding piles special treatment, especially if they resist reduction. External piles are of two varieties: (1) external tags of skin; (2) venous tumors. External tags of skin, when inflamed, constitute one of the most painful varieties of piles. An ordinary prescription can do but little good. Ointments cannot be absorbed. The application of heat or cold is productive of more positive results. Use flaxseed poultices or cloths wrung out of hot water and changed often. If heat is unpleasant to the part, apply very cold water in the same way. If an astringent is necessary, make solution of sugar of lead; bowels should be moved daily, salines as good as any. An injection of a quart of cold water will afford some relief. A radical cure consists in the removal of the tumor. Never try to push tumor inside of the rectum. The treatment of internal piles is different from the class just cited. The danger from this class is hemorrhage or strangulation; either may endanger life. An indiscriminate prescription of an ointment accomplishes nothing. Far better is an application of cold water when not protruded. An injection of cold water when not protruded but painful gives more comfort than all the combination of ointments usually prescribed. If, when the person who is troubled with the protrusion of internal piles is directed to take a cold-water injection every morning to move the bowels, to bathe the pile tumor in cold water after an evacuation, anoint the mass with plain vaseline, then push it back, and under no circumstances to use paper as a detergent, much comfort will be gotten out of these directions.

If internal piles both bleed and protrude, a little different treatment is used. The hemorrhage must be looked to. When protruding, an examination can be made, and if no bleeding points are found the following will be found good:

℞ Vaseline..... 1 ounce.
Acetate lead.....20 grains.
Pulv. opii.....15 grains.
Balsam Peru..... 1 drachm.
M. Sig.: Apply to pile after washing with cold water.

If protruding external piles are accompanied with much pain, some complication exists; usually ulceration. Washing with hot water will be found more agreeable, to be followed by the following prescription, which contributes much to relief:

℞ Cocaine..... 7 grains.
Extr. opii.....20 grains.
Extr. belladonnæ.....16 grains.
Lanoline..... 1 ounce.
M. Sig.: Apply after washing. Then return mass.

At bed-time use the following suppository:

℞ Iodoform..... 4 grains.
Morph. sulph.....½ grain.
M. ft. sup. No. 1. Sig.: Insert at bed-time.

Itching is often mistaken for piles; if itching is a most prominent symptom, it will most likely be found to be pruritis If with piles we have an itching of the surrounding parts, the following is suggested:

℞ Vaseline..... 1 ounce.
Ichthyol..... 1 drachm.
M. Sig.: Apply often.

—*Matthew's Med. Quarterly.*

RHINOLITHS: WITH CITATION OF A CASE.

C. ROBERTS BINDER, M.D.,* PHILADELPHIA, PA.

The semeiological factor of rhinolith is a purulent rhinorrhœa attended with fetor, the degree of which is proportionate to the length of time of lodgment and to the treatment. The treatment may be by either a domestic or a professional detergent. The diagnostic feature recounted may be accompanied, singly or jointly, with frontal, orbital and superior maxillary pain. These pains are not always caused by the obstructive nature of the mass damming the muco-purulent discharge due to inflammatory action and the physiological secretions from the nasal duct. The writer does not wish to claim that the pains are not due to retention of the secretions. He thinks that they are aggravated by the mass becoming firmer and larger, this predicament resulting in peripheral neuritis of the small nerve filaments ramifying over the nasal mucous membrane. The intermittent character of the pain, however, tends to disprove this assertion.

The analytical character of rhinoliths has been largely discussed, but rather unsatisfactorily. The chemical components, according to Demarquay and Bouchardat, consist of the phosphates and carbonates of lime and magnesia, with the chloride of sodium. The latter salt, according to investigation, appears in greater quantity when the rhinolith is in the inferior meatus, occluding the nasal duct. The secretion of the lachrymal glands is chiefly chloride of sodium, therefore the nucleus lodged in the inferior meatus, though small, but increasing in magnitude from the nasal secretions of mucus, fixed phosphate and carbonate of lime, together with a trace of amorphous fats, would be an incentive for the sodium chloride to unite and form a chemical compound of these salines. On the contrary, when the nucleus is in the middle meatus the nasal duct is not occluded unless the rhinolith attains a very large size. Consequently position has considerable influence as to the chemical nature of a rhinolith.

The gouty diathesis is the sole explanation of a rhinolith occurring spontaneously, and in my observation this can only be accounted for by calcareous degeneration, according to the theories of Virchow and Kölliker. These atheromatous conditions usually result in renal calculi or bladder masses. Let me add that a chronic ulcerative inflammation upon the turbinated bones would also produce this condition, but it is rare to see chronic ulcers with cheesy deposits in this region.

McBride speaks of "clots" as forming a nucleus for rhinoliths. A statistical list of this class is not obtainable at present, but it would be interesting to know to what degree epistaxis is directly the cause of rhinolith. From my own observation it is infrequent.

Masses of necrosed bone is responsible for many rhinoliths. These bodies usually form in the accessory cavities—antrum, frontal sinuses, ethmoidal and, rarely, spheroidal cells. From these cavities they find their way into the nose. The aged suffer from this causal factor more than do the young.

Inspissated material is also given a place as a nucleus. But, then, there must be an atrophic condition previous to development of rhinolith. In this category may be mentioned Virchow's process of calcification in disintegrated and cheesy tissue. The author would favor the latter views more readily than the former, since the presence of desiccated mucus is only coincidental. Facts prove that rhinoliths are connected with a hypertrophic rather than an atrophic rhinitis, due unquestionably to the alert and speedy diagnostician, who discovers the foreign mass before it is allowed to develop atrophy. Several cases, however, are on record where the rhinolith was in active accumulation for ten years. I myself have been fortunate enough to see one of nine years' standing.

The size of these extraneous masses varies according to the nuclei and the time length of development; also to the activity of the secretory powers of the patient.

The most likely causal factor—in fact, despite the contention of some authorities, it should be termed to-day *the causation*—is a foreign body. These foreign bodies consist of every conceivable article that

* Chief Assistant of the Laryngological Clinic of the Medico-Chirurgical Hospital.

can be thrust into the nose, from the time the creeping child knows that he has this organ until the freakish pranks of adolescence are passed. Such are beads, beans, shoe-buttons, and a prime favorite among small children are cherry-stones; also may be mentioned the small pebble found on the sand beaches of the fashionable watering resorts.

The nucleus determines the size entirely, for the coating of saline is very slight, even in cases of long standing, not exceeding a covering of two to four millimeters in a decade. But this shell-like covering or coating is not uniform in thickness, for sometimes from the outside of the nucleus to the top of the rhinolith the measurement equals two centimeters. Of course this occurs when the mass is spiculated, and is in reality the measurement of the spicula. Sometimes rhinoliths have attained unusual size. Seiler reports a case in which the length measurement was 3½ inches and the width ¾ of an inch, weighing in all 46 grains. Unfortunately a lithotrite was used to extract this calcareous body and consequently, or in all probability, the nucleus was lost. Some years ago a case was reported by Ashhurst, of the University of Pennsylvania, the weight of the extracted mass being one ounce. Lithotrites, while of absolute necessity in extracting and crushing bodies of large size, are responsible for the deficiency in literature on the subject of rhinoliths; and as a consequence the exact origin is also obliterated, especially if the etiological factor is a nucleus.

The shape of a rhinolith, according to my observation, is entirely dependent upon the nucleus and the position that this foreign body has assumed within the lumen of the nose. For instance, if the nucleus lodges in the inferior meatus, the calcareous mass increases in its spheroidal limits, according to the cast—foreign body—over which the mass is forming, with spicula extending between the inferior surface of the inferior turbinated and the inner surface of the mucous membrane of the superior maxillary bone. Naturally, the molding is modified by the anatomical condition of the internal structure of this organ.

When the nucleus is lodged in the middle meatus the nasal calculus is of a triangular formation, in appearance much like a stellated body, as the spicula projects laterally between the superior margin of the inferior turbinated and the inferior anterior margin of the middle turbinated respectively and posteriorly downward toward the floor of the nose, while a solid calcareous mass usually fills the olfactory cleft. As to the formation of nasal calculi in the accessory cavities, their shapes are rather vague and undoubtedly disguised by assuming, finally, a position in the nasal lumen.

The symptomatology of rhinoliths, as observed by most clinicians, is the usual fetid, sanguineous and unilateral discharge. Double rhinolith is extremely rare. There is no dyscrasia, though I have seen a case of the latter sort, which I will remark later. Pains, if there are any, are as a rule frontal or orbital. Hemorrhage of the nose is not infrequent.

An interesting case is recorded at the Medico-Chirurgical Hospital. The case presented itself to Dr. Arthur H. Cleveland for inspection. The usual prime symptom was uppermost—a fetid discharge from the right nostril accompanied with pain referred to the frontal region.

L. R., age fourteen years; suffering from a catarrhal affection of the right nostril for nine years. The affection was noticed by the mother when the child was five years of age. The probe gave the hard metallic ring upon sounding, thus satisfying the operator that it was not a sequestrum. Further inspection and washing brought to light a well-formed and large-sized calculus, perhaps one and one-half decimeters in diameter, which was removed with little difficulty and was followed by slight hemorrhage. The calculus was a splendid specimen of the spiculated order. The nucleus was found to be a cherry-stone, the result of a childish prank. The dyscrasia which appeared in this case was, I think, due to the irritability and peevishness of the patient—a result of the constant frontal pain. There was some discoloration of the skin covering the angle of the jaws; the nose, which was markedly platyrrhine, was somewhat discolored. A complete recovery followed the extraction.

Signs of the Times.

A man is lingering at the gate—
Some tramp or burglar, maybe;
Oh, no, he is a candidate—
He wants to kiss the baby.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE AMERICAN JOURNAL OF OBSTETRICS

for October. Dr. George H. Rohe, of Catonsville, Md., contributes a paper on

Intestinal Obstruction Following Operations in which the Peritoneal Cavity is Opened.

Obstruction of the bowels causes between 1 and 2 per cent. of the deaths following ovariotomy and other operations involving opening of the peritoneal cavity. The author states that he has been able to collect in the literature and from personal communications no fewer than 75 deaths from this cause. He divides secondary or post-operative intestinal obstruction into two classes of cases, one due to mechanical causes—adhesions, peritoneal bands, volvulus, accidental fixation by sutures, etc., and perhaps compression in exudation masses—and another due to paralysis of peristaltic movement of the intestines following sepsis or injury to the nerve supply of the muscular coat. The obstruction may be acute—*i.e.*, occur immediately after or within a few weeks subsequent to the operation—or it may develop gradually and not become complete until months or years afterward.

The majority of cases in which the cause of the obstruction was ascertained by operation during life or by necropsy, have been found to be due to abnormal fixation of the intestines by adhesions or to compression by peritoneal bands or cords inflammatory in origin. Any hindrance to the passage of the contents of the bowel at the point of flexure causes dilatation above and consequent increase of the degree of flexion. When this occurs there is at first increased peristalsis, but if the obstruction is not soon overcome the circulation is interfered with, dilatation of the bowel with paralysis of its walls follows, and the anatomical picture of the obstruction is complete.

Volvulus sometimes occurs after abdominal section, but probably only after some previous adhesion or constriction of the bowel.

There seems to be no question that by far the larger proportion of cases of post-operative intestinal obstruction are due to adhesions of the intestines to each other, to the abdominal walls, or to other viscera.

The symptoms are essentially the same as those of primary obstruction; but they are often marked by pain, vomiting and tympanites—so frequently present after abdominal operations without being significative of obstruction. Unless the obstruction is due to some untoward occurrence in the technique, the significant symptons are not likely to be present for several days subsequent to the operation. If a patient does well for three or four days or longer after an abdominal section or vaginal extirpation, and is then suddenly attacked by pain followed by vomiting, tympanites and inability to pass feces and flatus, the diagnosis of intestinal obstruction is probable. If the vomiting becomes fecal, the pulse rapid, the urine scanty, and symptoms of collapse set in, the diagnosis becomes reasonably certain. All these symptoms, however, are not uniformly present in obstruction. When the obstruction is high up in the small intestines fecal vomiting is usually absent and distention is likewise less marked. In these cases, also, the bowels may move several times after the pain begins, so that the diagnosis may be more or less uncertain.

An important point is the occurrence of local distention of the bowel above the point of occlusion in mechanical obstruction. This distention begins at the point of obstruction and extends upward along the course of the bowel. In mechanical obstruction, therefore, if the case can be observed from the beginning, there will be found an elastic swelling localized at a point of the abdomen and gradually enlarging, the direction of increase in size being along the course of the constricted bowel above the constriction. The distention is attributed to rapid decomposition of the arrested intestinal contents. Coincident with this local meteorism is an increased peristaltic movement of the bowel, also above the obstruction. In the later stages, particularly if septic peritonitis with paresis of the intestinal walls has occurred, these diagnostic signs are no longer available. In cases of obstruction due to paralysis of the intestine from the beginning (probably always a consequence of septic peritonitis) these symptoms are not present. Here there is a uniform globular distention of the abdomen without movement of the intestines, and without noticeable contours of the bowels through the abdominal walls.

An additional sign is furnished by the urinary reaction. It is claimed that in complete obstruction of the ileum there is always indican in the urine. In obstruction of the colon or high up in the small intestine this reaction is usually not present. The reaction is obtained by boiling a small quantity of the urine in a test-tube and adding nitric acid *guttatim*. The urine turns to a Burgundy-red color, and a similarly colored precipitate is thrown down. If urine yielding this reaction is shaken a violet-colored foam is produced. So long as this remains the case is a grave one. If, after operation for relief of the obstruction, the reaction persists, the obstruction has not been removed. In cases where the obstruction is relieved the reaction disappears within twenty-four hours. While this sign must be regarded as a very important one, it is not absolutely pathognomonic,

as a similar reaction occurs in some other morbid conditions.

The prognosis of primary intestinal obstruction is sufficiently grave. Following closely upon an operation so serious as abdominal section or vaginal extirpation of the uterus, this gravity is enormously increased. The abdominal surgeon should therefore be prepared to promptly recognize and appropriately treat this unwelcome complication. The knife is not always to be resorted to at once in the treatment of this condition, but when other means fail to give relief the surgeon should not hesitate to operate, as delay, in cases not otherwise curable, always increases the danger of operative measures. Cases occur where the symptoms may point to obstruction by means of adhesions, peritoneal bands or volvulus, and yet there is a possibility that there may be simply functional obstruction. In such cases other means may be tried until it is found that they are ineffective.

The author condemns the so-called "medical treatment" by means of opium or drastic purgatives. But certain procedures are frequently indicated, and though they are not often curative, certainly give temporary relief. Such measures are stomach-washing, rectal inflation of gas or air and injections of fluids. In stomach-washing some mild antiseptic lotion containing boric acid should be used. The lavage may be repeated every four to six hours as the vomiting or distention demands. The author also mentions the following method of Klotz: As soon as symptoms of obstruction appear the stomach is washed out with from four to six quarts of warm salt solution. Should this fail to relieve the symptoms it is repeated and a large dose (one and a half to two ounces) of castor oil is passed into the stomach through a tube. In all cases so treated by Klotz the active peristaltic movements set up caused passage of flatus and feces within ten hours. Evidently it is only in cases of fresh and friable adhesions that this method can be successful.

Rectal injections of water or air may at times be curative when the obstruction is due to intussusception, volvulus or to soft adhesions of the lower portion of the intestine, but where the obstruction is due to cords or bands they can manifestly be of no avail. They should therefore not be pushed beyond a reasonable trial. Care must be taken not to use too much pressure in making rectal injections, for fear of rupturing the bowel. Attempts to force the ileo-cecal valve must be regarded always as ill-advised. Too much care cannot be used in passing a rectal tube high up into the colon, as the author has seen one instance of perforation of the sigmoid flexure where this was attempted.

The rational treatment of intestinal obstruction following abdominal section is to reopen the abdomen, seek for the place of obstruction, relieve the same by separating adhesions, dividing constricting bands or untwisting a volvulus. If the gut is much distended an incision to let out the gas and fluid feces may be made and the bowel afterward carefully sutured. Gangrenous intestine must be resected and the ends joined by suture or Murphy's button. If the obstruction is due to a volvulus it would probably be always advisable to resect the twisted portion of the gut, as the volvulus is extremely likely to recur.

When practicable it is probably always best to make the incision in the middle line, as it permits more thorough and ready exploration of the abdominal cavity. Search should first be made for the obstruction in the iliac regions, as here obstruction is most likely to occur. If not found in either of the iliac fossæ and if it cannot be located by local distention, the entire length of the intestine must be passed through the fingers until the constriction is found. As it not infrequently happens that there is more than one point of constriction, the examination should be thorough.

The Relation of Hysteria to Structural Changes in the Uterus and its Adnexa

is discussed by Augustus P. Clarke, A.M., M.D., of Cambridge, Mass. From his own observation and experience gained in the treatment of cases of hysteria, the following propositions have been formulated:

That in the large proportion of cases of genuine hysteria there exists some distinct and tangible lesion of the uterus, appendages, or of parts immediately connected, and that the hysterical phenomena resulting from such organic disturbance will not yield until definite measures have been instituted for overcoming the original malady.

That in some cases the impoverishment of the blood and other constitutional influences may give rise to paroxysms of hysteria.

That these attacks are often transient, much more mild, and when properly treated by constitutional measures may disappear altogether.

That in those more obstinate cases of nervous perversion in which there may exist to a greater or less extent hyperesthesia, anesthesia, analgesia, and the like, the disease may not be necessarily dependent on factors giving rise to the disease in question, but may be of the nature of epilepsy or of insanity, or be dependent in whole or in part on morbid processes connected with some portion of the sensorium.

That the diagnosis of such cerebral lesions will be strengthened when, in the absence of a manifest organic disturbance of the genital tract, there is a history of a severe blow or injury to the head, or of influences or factors which have produced a profound or prolonged impression on the encephalic centers.

That in hysteria, on the other hand, none of these conditions exists; the phenomena are merely the result of reflex movements which occur for the most part during the period of the greatest activity of the organs of reproduction. That at such a time a seemingly limited amount of tumefaction, or an adhesion of a tube or ovary, or an adventitious change in the shape or relation of the uterus, is capable of effecting constitutional as well as local disturbances of the nervous centers.

That though hereditary predisposition may

to some extent be an exciting cause of hysteria, such an influence as an original factor should nevertheless be regarded as unimportant.

That when hysteria occurs later in life it is *prima facie* evidence that the genital tract has become diseased or has taken on a preternatural condition.

That if, after careful examination, such a diagnosis of local physical obliquity cannot be established, we should, though the patient suffers from perverted sensations referable to the nervous tracts, be suspicious that disease has taken lodgment in some portion of the encephalon or the organism under a more immediate control of the central nervous system.

C. C. Frederick, B.S., M D., Adjunct Professor of Obstetrics, Medical Department Niagara University, etc., Buffalo, N. Y., discusses

The Relations of the Minor to the Major Diseases of Women.

In regard to which are the minor and which the major diseases of women, he considers malignant disease of the uterus, and any condition or growth of the pelvic organs which necessitates opening of the peritoneum for its cure, a major disease. All the rest are minor. The principal minor defects of the female genitalia consist of lacerations of the perineum and pelvic floor, lacerations of the cervix and backward or downward displacements of the uterus. These tend to produce an endometritis or to aggravate a diseased endometrium and favor the development of endometrial septic processes and their deleterious effects. The author admits that a torn perineum may exist for years without discomfort to the patient or any visible effects on her pelvic organs. So long as it does no harm it needs operation only as a preventive measure. When the uterus becomes misplaced as a consequence of the tear the displacement should be corrected by means of a pessary, or if this will not be retained the perineum must be repaired. If a cystocele or rectocele exist, anterior and posterior colporrhaphy should be done at the same time as the perineorrhaphy. A lacerated cervix, with ectropion and hypertrophy of the lips, is one of the most fertile sources of disease of the endometrium. Soothing applications give only temporary relief. The only permanent relief is to be had by curetting the uterus and repairing the laceration. Then replace the uterus and hold it in position till involution occurs, and the cure will be complete. The author takes a firm stand against intra-uterine medication as useless and often positively harmful as ordinarily practiced. It may be safely said that the dirty sound and intra-uterine medication have caused more serious disease in women than the conditions for which the treatment was given would ever have caused.

In the treatment of these cases constitutional treatment should not be forgotten. Tonic treatment will do much for some of these cases. The author states that he has often seen several malarial subjects with profuse uterine catarrh entirely cured by anti-malarial treatment.

True endometritis is best treated by thorough dilatation of the cervical canal, removal of the diseased membrane with the sharp curette and thorough disinfection of the cavity. It may then be packed with iodoform gauze to insure good drainage. The author insists that, in spite of all that has been written to the contrary, the operation is as safe as any in gynecology, provided there is no extensive disease of the uterine appendages. Of course the operation is to be done with full antiseptic precautions.

The author closes his paper as follows: "Prevent puerperal infection by practicing antiseptic midwifery; discourage abortions on the part of your patients; have your patients' lacerated cervices and perinei repaired before they lead to diseased conditions; build up your female patients' general health; do very little or no intra-uterine medication; cure their endometritis, whether due to gonorrhœa or other causes; correct displacements, if there be no chronic tubal or ovarian trouble or adhesions, and you will prevent much of the pelvic disease for which hundreds of capital operations are done every week, and you will have answered the question, 'What can I do to prevent so much pelvic disease?'"

Dr. J. H. Carstens, Professor of Obstetrics and Clinical Gynecology in the Detroit College of Medicine, etc., contributes a paper on

The Incision in Abdominal Surgery.

A summing up of the author's methods is as follows:

1. With a small, narrow-bladed, sharp knife make a clean incision through the skin of the necessary length, and with another sweep (or two) cut through the linea alba, muscle, etc. Lift the peritoneum with your fingers, open it and enlarge the incision. The use of forceps to lift the tissues, or the grooved directors, is unnecessary.

2. In closing the abdominal incision use animal ligature, kangaroo tendon or catgut. First carefully bring together the peritoneum in a running stitch, then the transversalis fascia, and the rectus if the incision is through this muscle. Then most carefully bring together—edge to edge—the tendinous insertion of the oblique muscles. The loose cellular tissue above and fat can be brought together in one or two tiers, according to thickness. Bring the skin together carefully with Marcy's cobbler's stitch, thus burying all your sutures.

3. Then seal with collodion, and if everything connected with the operation has been perfectly antiseptic, absolute primary union will take place, the different layers of the abdominal wall will have been brought together as nearly as possible as they were in the first place, and no hernia will result.

4. In cases of extensive umbilical, ventral or other hernia it is best to bring the peritoneum together with an over-and-over stitch of kangaroo tendon or catgut; to make a flap-splitting operation of the ring, which is brought together with silkworm gut or silver wire, which is buried, and then the fat and

skin are united with the buried animal suture.

Two papers appear in this issue on

Catheterization of the Fallopian Tubes.

The author of the first paper, Llewellyn Eliot, A.M., M.D., of Washington, D. C., discusses two propositions: 1. It is possible to catheterize the Fallopian tubes. 2. The possibility being established, the attempt to treat cases of diseased tubes by applications made directly to their surfaces is justifiable. The author quotes cases to prove that the first proposition is true and therefore the second becomes self-evident. Still he is obliged to confess that it is not possible to catheterize the tubes in every instance, and that the procedure is not free from danger. The method is applicable, he thinks, to those cases of salpingitis, hydro- and pyo-salpinx which refuse operation.

The second paper on this subject is from the pen of William P. Carr, M.D., of Washington, D. C., and in it the author enters into the dangers of the procedure and cautions against perforation of the uterine or tubal wall, or the forcing of pus into the peritoneal cavity. With its limitations he cannot predict a brilliant future for the operation.

Two papers are also devoted to the subject of

Puerperal Insanity.

The first, by George Byrd Harrison, M.D., of Washington, D.C., deals with the causation and symptoms of the disease. Of the symptomatology of puerperal insanity he says that there is none *per se*. Of course with the aid of physical examination and other outside proof, we may differentiate the mania and melancholia associated with the childbed state from the other and commoner forms of the same disease. But they have no positive characters of their own. Even the "consciousness of a delusion," which has been elaborately dwelt upon, can scarcely be accepted as a shibboleth. Examination of the patient and the history of the case can alone be relied upon for differential diagnosis.

The second paper, by William Mercer Sprigg, M.D., Professor of Physiology, Medical Department National University, Washington, D C., deals with the prognosis and treatment of the disorder. The early routine treatment of these cases by blood-letting, purging, blistering, etc., is interesting only as a relic of the past. The breasts usually do not require attention, as nature, without assistance, shuts off the supply of milk. Abscess of the breast in this condition is most unusual. The anemia should be treated with food and the iron preparations, together with good hygiene, sunlight and fresh air. The bowels should be kept open daily. If the iron preparations fail in their effect Fowler's solution of arsenic might be used. Sedatives and hypnotics should be used with caution, as a supporting, not a depressing, treatment is indicated. In severe cases with coated tongue, great nervous and vascular depression, neither opium nor chloral should be used. Morphia, hypodermically, a single full dose at bed-time, will usually insure rest. A hot bath, followed by a good rubbing and a glass of hot milk, will sometimes have a very quieting effect if given at bed-time. Hydrobromate of hyoscine has been used hypodermically with good results. The bromide salts have a prominent place in the treatment. Stimulants should be given when the pulse is weak and nutrition defective—and given for physical and not for mental effect on the patient. Mental diversion or entertainment should occupy an important place in the treatment. The bringing on of premature labor is to be condemned.

Eugene Boise, M.D., of Grand Rapids, Mich., discusses "The Cause of the Thirst Following Abdominal Sections." The theory advanced is that it is caused by contraction of the arterioles of the abdominal viscera, and consequent lessened tension in their capillaries and compensatory withdrawal of water from their tissues, all of which is due to the irritation of the abdominal sympathetic nerves during the operation.

The remaining papers in this issue are: "Stray Thoughts on the Mechanism of Labor," by A. F. A. King, M.D., Washington, D.C. "One Year's Death Record in Abdominal Surgery," by J. H. Carstens, Detroit, Mich. "The Management of an Ordinary Case of Labor in Hospital and in Private Practice," by Francis Smith Nash, M.D., Washington, D.C.

IN THE BRITISH JOURNAL OF DERMATOLOGY for October Dr. W. Allan Jamieson writes of

Some Rare Skin Diseases.

The author was consulted by a man of 55 years, rather fat; had been accustomed to use alcohol; was subject to rheumatic gout, but had enjoyed pretty good health. Of late the patient had tired easily, slept poorly, arose in the morning with a thickly coated tongue. His appetite had been failing for about one year, and although he consumed considerable liquid it was not owing to any great thirst.

The dimensions of the liver and the action of the bowels seemed normal. Urine was acid, copious, sp. gr. 1.010, without deposit or discoverable tube casts, but containing small quantities of sugar and albumen.

An irritable eruption was complained of; had appeared two or three years before; itched always, but worse at night. Examination showed a discrete, symmetrical eruption of oval or stellate form, solid elevations, some almost the size of a split pea. The color was pinkish or reddish-brown, sometimes with a yellowish or brownish marginal line around a pink center. They did not wholly vanish on pressure. The hands, face and mucous membranes were free, but the outer aspects of the forearms, the shoulders, back and, to a less extent, the chest and abdomen were affected. The flanks contained a couple of leucodermic areas.

The patient was ordered to stop arsenic, which he had been using, was put on a selected diet, told to wash with menthol soap in the morning, and to apply at night a solution of one part ichthyol in three of water, and to take a pill of a quarter of a grain each

of codeine and extract of lactucarium and one-half grain of extract of nux vomica. He improved under this, but the dose of codeine could not be increased. The symptoms all improved, but after the rash had disappeared with the exception of a few stains, sugar and albumen might still be found in the urine.

Xanthoma diabeticorum usually selects the knees, elbows and buttocks, and the eruption when colored is usually yellow. None of these characteristics appeared in this case.

One authority states that the eruption may lose the yellow color as it grows older, but even the new spots in this case were pink.

A case of hydroa vacciniforme sen æstivale is reported, peculiar in the patient being a girl of eight years, and with very great scarring from healed vesicles. The application of borated starch poultices, followed by painting with zinc-ichthyol jelly, seemed beneficial, but the case passed from observation.

Another case reported was a woman 54 years old, in whom the menopause occurred four years previously, who complained of itchiness and burning heat in the vulva. It was found that a patch of scleroderma contracted the arms and passed forward on the perineum, and had caused a linear ulcer. A small patch of scleroderma was found on the prepuce of the clitoris, another on the right leg, running from the patella half-way to the ankle, a large patch over the ribs on each side (in front), and two more above each clavicle, looking like inlaid ivory.

Dr. Stephen Mackenzie had a paper on

Acne.

which was freely discussed.

The disease he thinks due to faulty secretion by the sebaceous glands, consequen-plugging of the ducts and inflammation from retained secretion.

The treatment he thought should be strictly local and should consist in the removal of superfluous sebum and epithelial accumulations; stimulation of the glands to healthy activity; keeping the skin aseptic to exclude pus cocci. Various medicated soaps met the requirements thoroughly, and should be accompanied by bathing the face in hot water and steaming.

Ointments and lotions are useful to allay inflammation, zinc and belladonna being noteworthy in this class.

During the discussion, most of those present seemed to think that, if not dependent on constipation and indigestion, acne was usually accompanied by these disorders, and the cure was hastened by appropriate treatment for these.

IN THE JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for October Dr. William H. Kingston writes of

Stone in the Bladder—Choice of Operation.

The author's experience leads him to think that in all cases where the urethra will admit or can be made to admit a lithotrite, litholopaxy is superior to cutting; that this method is applicable to older men and to younger children than it was formerly thought to be, and that improved instruments permit the crushing of larger and harder calculi than formerly; that in women dilatation of the urethra is usually sufficient to permit extraction without crushing; that in those cases where the size of the calculus is doubtful and cutting is found necessary, it is more prudent to choose the suprapubic operation, as the stone might be too large for the lateral incision. When cutting is necessary the author expresses himself in favor of the lateral incision when practicable, but fails to state what circumstances would cause him to choose this, in adults, instead of litholopaxy. It appears objectionable to break a stone before removing through an incision.

Dr. George Thomas Jackson writes of

Thyroid Feeding in Diseases of the Skin.

The author used thyroid preparations in a few cases of xeroderma and dermatitis exfoliativa, and finding unpleasant constitutional symptoms from the drug and no permanent improvement in the disease, thinks this treatment unsuited to anything so trivial as a skin affection.

Drs. J. Abbott Cantrell and Emanuel J. Stout conclude their paper on "Favus of the Head and Body."

Erysipelas.

During a long practice I have found the following local application most excellent:

℞ Aquæ puræ ..... Oj.
Ferri sulphatis. q. s. facere solutioneum ad saturandum.
M. Sig.: Keep a cloth wet with the mixture to the parts affected.

℞ Iodoformi ..... ʒj.
Olei rosæ ..... gtt v.
Collodion ..... ʒx.
M. Sig.: Use as a local application four or five times daily. The burning pain is relieved at once.

℞ Acidi carbolici (liquid) ..... } āā ʒj.
Spir. vini rectificati ..... }
Tincturæ iodini ..... }
Olei terebinthinæ ..... ʒij.
Glycerini ..... ʒv.
M. Sig.: Paint parts affected three or four times daily.

℞ Salol ..... ʒij.
Iodoi ..... ʒj.
Glycerini ..... } āā ʒj.
Collodion ..... }
M. Sig.: Apply to affected surface three or four times daily.

—*Dr. N.B. Kennedy in the Texas Sanitarium*

Chronic Conjunctivitis of Eczematous Patients.

Dr. Von Sehlen (*La Semaine Medicale*) speaks highly of the following salve in the occasionally chronic conjunctivitis of eczema:

℞ Ichthyol	0.20-50	o (grs. iij-viij).
Powdered starch	10	o āā (ʒijss).
Oxide zinc		
Vaseline	25	o (ʒvj).

Mix very carefully.

The salve is applied to the palpebral conjunctiva by means of a little glass rod. If it has been well mixed and the ichthyol be equally distributed through the vaseline, only a slight burning sensation will be experienced. Under its influence obstinate eczematous conjunctivitis, often leading to ectropion, will be rapidly cured—*Pritchard.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE

An Old Medical Protest Against Railroad Trains.

According to *La Medecine Moderne*, there is preserved at Nuremberg, in the archives of the first railroad company built in Germany, a protest offered at the time of the construction of the line, by the physicians of Bavaria. Among other reasons given for opposing the scheme is this psychological one: "Traveling in vehicles drawn by a locomotive ought to be forbidden in the interest of public health. The rapid motion cannot fail to produce in the passengers the mental affection known as *delirium furiosum*. Even when travelers consent to expose themselves to this danger, the government at least is in duty bound to protect the public. A single glance thrown upon a locomotive passing at great speed is sufficient to cause the same cerebral derangement. It is accordingly absolutely necessary to build a fence three meters high on each side of the railway tracks."—*Boston Medical and Surgical Journal.*

Methyl-violet in Diphtheria.

Methyl-violet is practically unirritating to the faucial and gastric mucous membranes, and can be used in almost any desired strength as a topical application, or may be administered internally in pill form in doses of one-tenth grain to one grain, from one to three times a day.

As a local application to the throat in diphtheria a solution is used, the strength of which may vary from one to ten per cent., usually a two per cent. solution. The effort is made to apply the solution, by means of a cotton swab, as accurately as possible to the diseased area. It is not, however, possible to limit the agent in most cases to the diseased spot, but the healthy mucous membrane becomes deeply stained by the agent.

It was used in twenty-six cases of diphtheria and only two died, both of which had laryngeal involvement.—*W. P. Munn (Denver, Col.) in Pittsburg Med. Rev.*

The Glycosuria of Pregnancy.

It is as well to know that the appearance of sugar in the urine of puerperal women is not, *per se*, to be accepted as evidence of any morbid condition calling for urgent measures. Sugar, in greater or lesser amount, is present, according to Dr. Lewers, in the urine of most puerperal women, but even when comparatively abundant its presence was not associated with the classic collateral symptoms of glycosuria. The amount indeed stands in some sort of relationship to the lacteal secretion, or rather excretion; when the flow is free, whether copious or otherwise, the amount of sugar discoverable in the urine is small. If, however, the output of milk is checked in any way, mechanically or otherwise, a certain proportion of the lactose is eliminated by the kidneys, giving rise to passing glycosuria. Belladonna, probably by reason of its effect in diminishing the excretion of milk, increases the percentage of urinary sugar. It is to be supposed that the glycosuria disappears when lactation comes to an end, but as a matter of fact it has seldom been possible to continue the observations a sufficient length of time to ascertain it by direct examination.—*Medical Record.*

The Dietetic Treatment of Phthisis.

Dr. Henry P. Loomis formulates the following rules:

1. Never take cough mixtures if they can possibly be avoided
2. Food should be taken at least six times in the twenty-four hours; light repasts between the meals and on retiring.
3. Never eat when suffering from bodily or mental fatigue or nervous excitement.
4. Take a nap or at least lie down for twenty minutes before the mid-day and evening meals.
5. Take only a small amount of fluids with the meals.
6. The starches and sugars should be avoided; also indigestible articles of diet.
7. As far as possible each meal should consist of articles requiring about the same time to digest.
8. Only eat so much as can be easily and fully digested in the time allowed.
9. As long as possible systematic exercise should be taken to favor assimilation and excretion; when this is impossible, massage or passive exercise should be undergone.
10. The food must be nicely prepared and daintily served—made inviting in every way.

He proposes the following as a diet-sheet in the early stage: On awakening, eight ounces of equal parts of milk and seltzer, taken slowly through half an hour. Breakfast: Oatmeal and cracked wheat with a little sugar and an abundance of cream, rare steak or loin chop with fat, soft-boiled or poached egg, cream-toast, half pint of milk, small cup of coffee. Early lunch: Half pint of milk or small teacup of squeezed beef-juice with stale bread. Mid-day meal: Fish, broiled or stewed chicken, scraped meat ball, stale bread and plenty of butter, baked apples and cream, two glasses of milk. Afternoon lunch: Bottle of kumyss, raw scraped beef sandwich, or goblet of milk. Dinner: Substantial meat or fish soup, rare roast beef or mutton, game,

slice of stale bread, spinach, cauliflower, fresh vegetables in season (sparingly).—*The Practitioner.*

The Treatment of Sciatica.

Dr. Græme M. Hammond, of New York (*Post-Graduate*), discusses the treatment of rheumatic sciatica, or that arising from cold. In mild cases, ten or fifteen grains of phenacetine will usually afford relief; but in many cases this will not suffice Morphia should be given under the skin, and injected deeply into the part. Enough should be given to afford complete relief, as this seems to have a special action on the course of the disease. Perfect rest in bed will cut many cases short that might otherwise be very obstinate. The constant application of heat, as in hot rubber bags, is of the greatest value. The constant electric current is also an agent of much value in the treatment of these cases. Patients feel relief after each application.—*Dominion Med. Monthly.*

The Action of Calomel and Olive Oil.

Victor Schultz (*Berliner klinische Wochenschrift*) has noticed that in a patient upon whom a necropsy demonstrated that no gall-stones existed, a few hours after the administration of olive oil the gall-bladder, which up to that time had been soft and insensitive, became very tense, sensitive and painful, and then acquired that degree of painfulness which could be characterized as gall-stone colic. The significance of the fact is that the ingestion of olive oil is followed by a marked excretion of bile. As regards calomel, it has no influence upon a markedly increased biliary excretion; but rather, in gall-stones and diseases of the biliary passages, it acts not by increasing the biliary excretion, but by its disinfecting properties, thus diminishing the abnormal irritation of the mucous membrane of the gall-bladder.—*American Journal Med. Sciences.*

A Medical Library Association has been recently organized in Grand Rapids, Mich. The purpose of the association is the formation of a reference library upon medicine and allied sciences. The new organization starts out with a membership of about fifty, composed not alone of physicians, but dentists and pharmacists as well.

One of the features of the association will be the admission of non-residents to membership, whereby for a small annual fee physicians outside of the city may avail themselves of the advantages of the library.

A competent librarian will be secured and the most approved methods of cataloguing and indexing will be made use of. Books and journals are being liberally donated by those interested in the project, and the success of the enterprise is assured.

The following officers have been elected: Dr. G. K. Johnson, President; Dr. S. G. Milner, Vice-President; Dr. W. A. Dorland, Treasurer; Dr. Reuben Peterson, Secretary.

Terpene Hydrate in Bronchial Catarrh.

Dr. Murrell is desirous once more of calling attention to the value of terpene hydrate in the treatment of affections of bronchial and nasal mucous membranes. Its properties have been well known for many years, but in this country it has never been a popular remedy, and its claims seem to have been overlooked in favor of pure terebene and other similar compounds. It is a hydrate of turpentine, and is made by treating oil of turpentine with nitric acid and alcohol. It is a solid, and has somewhat the appearance of chloral hydrate. Its odor, which is slight, resembles that of pure terebene. For some months past he has prescribed it in solution containing five grains to the half ounce, made up with simple elixir and flavored either with tincture of Virginia prune and syrup of tar, or with the aqua laurocerasi. Terpene not only relieves cough and lessens bronchial secretion, but is a diuretic, and has been used with advantage in neuralgia. *La Tribune Medicale* recommends the following pill:

℞ Creosote... ..... } ää gr. j.
Terpene hydrate..... .... }
Iodoform..... }

Ft. pil. no. 1. Sig.: One pill three times a day, together with an inhalation of about two per cent. solution of eucalyptol every two hours.

—*Southern Clinic.*

Chloroform in the Treatment of Chorea.

When the convulsive movements of chorea are of sufficient severity to interfere with the indigestion of food, or sleep is prevented by the attacks, there is great danger of rapid exhaustion, and even death may be apprehended. In such cases chloroform will prove a veritable boon. Not only will the anæsthetic induce perfect relaxation and relief from the present attack, but the insensibility produced by it often passes into natural sleep, and the patient awakes refreshed and completely rested, with marked abatement of the hitherto constant movements. The improvement in some cases is marvelous. Not only is the sufferer allowed a much-needed rest by this means, but the attacks are delayed, their intensity mitigated, nourishment may be taken with relish, and a decided change in condition results. In the beginning, it may be necessary to use the chloroform three or four times daily, but as improvement occurs, only one administration in the twenty-four hours will be found necessary. Usually a month is required before the permanency of the cure is established.—*Louisville Medical Journal.*

Sterility.

Palmer: Gonorrhœa is one of the most frequent, even the most frequent, causes of sterility in the female; it exists often when not expected. Aside from gonorrhœa the most common cause is an imperfect development of the uterus. The organ is small, the cervix is elongated and concial, there is a pinhole os externum, and often anteflexion. Years

ago the treatment of the conoid cervix and pinhole os externum was to incise it; then followed the use of tents, but I think these have pretty well gone out of use; then came dilatation by means of the metallic dilator; and since we have had dilatation by means of galvanism. I have had several cases in the last ten years in which conception has followed the use of galvanism. In all cases there was more or less of conoid cervix and pinhole os externum. The case to which I particularly refer was one sent to me years ago. She had no leucorrhœa and was in good general health. I commenced the dilatation of the os externum and the cervical canal by means of galvanism. I passed one electrode through the canal and placed the other over the abdomen. The current was applied fifteen minutes twice a week for several months. After a married sterile life of seven or eight years she is now pregnant in her eighth month. I have seen similar results follow this treatment in other cases. The negative pole is used when one wishes to expand the cervical canal; the positive is a hæmostatic. I am disposed to think this is one the best methods of treatment in these cases, because it is comparatively painless, because it is comparatively safe, and because it leads to permanency of results which is not otherwise obtained.—*Arch. Gyn.*

Intracapsular Fractures.

Dr. Bedford Brown, of Alexandria, Va., gave the result of his experience with fourteen cases of femur, in a paper before A. M. A. He believes a good rule to work by in treating intracapsular fractures of the cervix femoris in the aged, is to so manage the case from the beginning as not to expect union of the fractured bones, but on the contrary to so conduct the management of the case as will, if possible, insure a good, strong false joint, by which after a time the patient can regain a fair degree of locomotion for the balance of life. To bring about this desirable object, the pelvis from the anterior superior spinous process is enveloped with a broad flannel roller four inches wide and fifteen feet long, applied down below the trochanters. This flannel bandage gives comfort by the support that it affords the fractured bones, and the prevention of too much motion, and gives opportunity to the soft parts involved to throw out adhesive exudations. This is the full extent of the apparatus to be applied. As for the balance of treatment, pillows long and short, small and large, are to be relied on for splints and supports. Comfort of position is to be the guiding rule in the management of this class of cases. The ingenuity of surgeon and nurse will be taxed to so arrange the pillow splints as to insure comfort, relieve pain and secure sleep. When these objects are accomplished all has been accomplished that judgment and experience can do until inflammatory action subsides and the process of fibrinous exudation is completed, and then the false joint is ready for use. To attempt, on the contrary, to confine this class of patients in a stiff apparatus with a view of accomplishing that which no power can eve effect—a union of bone or ligament—is to condemn our patient not only to unnecessary suffering, but to certain death.—*Richmond Jour. Practice.*

Paralysis of the Elevators and Depressors of the Eyeball.

Dr. Charles Wray in the London *Lancet*, gives two simple methods of pointing out the action of the four muscles involved in elevating and depressing the eye, and the situation of the false images when they are paralyzed. The action of each muscle, and the inclination of the false image when the muscle is paralyzed, are represented by four radii drawn from the center of the cornea, and forming a figure like the capital letter X.

For the examination of the action of these muscles the author sets forth the four following rules, which enable one to rapidly diagnose which muscle is paralyzed:

1. If the diplopia exists in the upper portion of the field of vision, the upper image belongs to the eye paralyzed.
2. If there is diplopia in the lower portion of the visual field, the lower image belongs to the eye paralyzed.
3. The paralysis of an oblique muscle gives rise to an internal strabismus and homonymous diplopia.
4. The paralysis of a straight muscle gives rise to an internal strabismus and crossed diplopia.

Treatment of Whooping-Cough.

Dr. G. Variot (*Lo Sperimentale*) has obtained notable advantages in the treatment of pertussis by the administration three times a day, in a little sweetened milk, of a teaspoonful of the following:

℞
Aq. dest.....8 ounces.
Potassii bromidi.....2 drachms.
Tinct. valerian.....2 drachms.

In children below two years a teaspoonful will suffice. An hour after this dose he gives a teaspoonful of the syrup of turpentine. The turpentine acts as a balsamic and the other drugs as anti-spasmodics. The presence of rales in the chest indicates ipecac in the powder form, a dose every morning to favor expectoration. Keep the child in the open air while there are no serious broncho-pulmonary symptoms. As a diet keep the child on albuminoids and meat, eggs, raw meat, extract of beef, etc., to which may be added some tonic, as the wine of cinchona or the syrup of the lactophosphate of lime.—*Lancet-Clinic.*

Thuja in Exophthalmic Goitre.

Dr. C. Sargent, of Taos, N. M., claims excellent results from treatment of exophthalmic goitre, with enlargement of thyroid the size of a hen's egg, with thuja occidentalis. In a brief period of time the result was marked by "no more eye trouble, no palpitation of the heart and the enlargement of the thyroid all gone."—*Med. Standard.*

SURGERY.

A New Operation for Procidentia Uteri.

In a short preliminary Dr. H. W. Freund (*Central. f. Gynæcol.*) calls attention to two cases of procidentia uteri cured by means of silver-wire sutures circularly drawn underneath the mucous membrane of the vagina. The sutures are placed in such a manner as to form a supporting pillar to the uterus, and tightened sufficiently to prevent prolapsus after replacement. The technique is simple. The silver wires, usually four or five in number, are drawn by means of a curved needle underneath the mucous membrane of the vagina, the first wire being about one inch from the os externum. The wire is carried underneath the mucous membrane to its full circumference, always re-entering the puncture of exit until it reaches the first puncture, when the portio vaginalis is pushed back by an assistant and the wire drawn tight, twisted and allowed to sink beneath the mucous membrane. In distances of three-fourths of an inch the sutures are introduced until the vagina is reinverted and the uterus replaced. Care must be taken not to allow any of the wire to lie on the surface lest suppuration and necrosis should follow.

In the two cases reported only local anesthesia was resorted to and the results were highly gratifying. The cases operated upon had both passed the menopause, and the author questions the advisability of using this procedure on women liable to become pregnant.—*Cincinnati Lancet Clinic.*

Cauterization of the Nares and Accidents that may Follow.

Dr. E. F. Ingals, of Chicago, believed that, when properly done, this operation is quite as free from discomfort or danger as any other minor surgical procedure. Serious results were due to carelessness or inexperience upon the part of the operator, which induced him to make extensive wounds or to repeat burnings too frequently. He summarized his conclusions as follows: 1. It is important that antiseptic applications be regularly employed after cauterization of the nasal mucous membrane, and that the nostril be closed by cotton for several days, whenever the patient is out of doors, to prevent taking cold. 2. As a rule, at least two weeks should intervene between operations upon opposite sides, and three or four weeks between those on the same side. 3. No serious results are at all likely to follow cauterizations made in this way. 4. Practically, all cases of hypertrophic or intumescent rhinitis may be cured by this treatment, though occasionally portions of the turbinated body must be removed. —*Journal American Medical Association.*

Treatment of Inoperable Malignant Tumors.

Dr. W. B. Coley, New York, in a paper before the meeting of the American Surgical Association, in Washington, D. C., reported twenty-five cases of sarcoma treated by inoculating the patient with the toxines of erysipelas and bacillus prodigiosus, with six cures. Nine markedly improved and eight slightly improved. Also eight cancer cases, all but one of which showed improvement. The author's conclusions were as follows:

First.—The curative action of erysipelas upon malignant tumors is an established fact.

Second.—This action is much more powerful on sarcoma than carcinoma.

Third.—This action is chiefly due to the soluble toxines of the erysipelas streptococcus, which toxines may be isolated and used with safety and accuracy.

Fourth.—This action is greatly increased by the addition of the toxines of bacillus prodigiosus.

Fifth.— The toxines, to be of value, must come from very virulent cultures and must be freshly prepared.

Sixth.—The results obtained from the use of these toxines, without danger, are so nearly, if not quite, equal to those obtained from an attack of erysipelas, that inoculation should rarely be resorted to.—*International Journal of Surgery.*

OBSTETRICS.

Concerning the Treatment of Abortion.

Eckstein (*Prager medicinische Wochenschrift*), as assistant in Martin's clinic, has had opportunity to study sixty cases of abortion treated by Martin's principles in his private clinic in Berlin. He attaches the greatest importance in the curettage of the uterus to the thorough emptying of the tubal angles, as remains of placenta or portions of membranes are especially liable to be attached there. In nearly all the cases Eckstein followed a manual or instrumental emptying of the uterus with curettage, by the idea that an imperfect separation of the decidua and a consequent endometritis is thereby to be prevented. The results of this method were very satisfactory. From his experience he deducts the following:

1. The instrumental method of the treatment of abortion is the only rational one.

2. The recognition of the cause of bleeding from the uterus is of the greatest importance, and therefore in every uterine hemorrhage a careful examination should be made.

3. Ergot and similar drugs should only be used when the uterus is empty.

4. If abortion is in progress, a tamponade of the vagina is only indicated when there is no dilatation of the os uteri.

5. When the dilatation of the os is sufficient, the emptying of the uterus, in spontaneous abortion, is indicated.

6. In large embryos, from the fifth month on, one conducts the abortion as in labor at term.

7. In abortion attended with fever and the decomposition of the product, the uterus should be emptied of its contents as quickly as possible.

8. A thorough curettage of the endometrium should follow every emptying of the uterus in abortion.— *Western Med. Reporter.*

Vinum Ipecacuanhæ as an Oxytocic.

A contributor to the *Brit. Med. Jour.* says: "In the course of general practice extending over many years I invariably carried a bottle of vinum ipecacuanhæ in my midwifery bag, and rarely, if ever, gave a dose of ergot in the first stage of labor. Time after time on coming to a confinement case where the pains had been feeble and inefficient or had totally ceased, two or three 10 or 15 minim doses of the wine at intervals of ten minutes had been followed in a surprisingly short time by energetic uterine action, with a rapid termination of the labor. It never produces the quasi-tetanic contraction so often met with as the result of ergot, the pains continuing to recur regularly, just as they do in natural labor, but with greater force and at shorter intervals. Conviction of the value of the drug for this purpose induces me to give my experience of it, believing that its merits will be recognized by any one who chooses to give it a trial."—*Med. Times.*

PATHOLOGY.

What We May See in the Sputum.

Microscopical examinations have so far superseded the older methods that we frequently overlook many valuable points of diagnosis that might be observed with the unaided eye. We may first observe the quantity, reaction and consistence.

Patients with bronchitis or cavities, and especially cases of bronchiectasis, have the largest quantity.

Unless contaminated with vomited matter, sputum is always alkaline.

Mucus sputum usually occurs early in acute bronchitis.

Muco-purulent sputum in chronic bronchitis and in phthisis, or in later stages of acute bronchitis and pneumonia.

Purulent sputum (nearly pure pus) indicates a cavity or an empyema.

Serous sputum is fluid, and contains albumen and is frothy. Characteristic of edema of lungs.

Blood expectorated from the lungs is usually bright red, frothy and alkaline. From the stomach it is dark, nearly brown, and acid in reaction.

Coal soot makes a black or gray sputum.

Fibers and pieces of lung tissue indicate a cavity.

Fibrinous casts indicate fibrinous inflammations. These are frequently found in croupous bronchitis.—*Kan. Med. Jour.*

ARMY AND NAVY.

CHANGE IN THE U. S. ARMY FROM OCTOBER 21, 1894, TO OCTOBER 27, 1894.

First Lieutenant Charles F. Kieffer, Assistant Surgeon, will be relieved from duty at Fort Assinniboine, Montana, upon the return to that post of First Lieutenant Edward L. Munson, Assistant Surgeon, from duty in the field, and will then report for duty at Fort Buford, North Dakota.

NEWS AND MISCELLANY.

The Horace Wells Anniversary Celebration.

All are doubtless aware of the action of the American Dental Association at its recent meeting held at Old Point Comfort, Va., with reference to holding a national celebration of the fiftieth anniversary of the discovery of the anæsthetic properties of nitrous oxide by Dr. Horace Wells.

The committee, by vote of the American Dental Association, was instructed to secure two papers to be read at the celebration; one upon the "History of Anæsthesia," by Prof. Thomas Fillebrown, of Boston, and one on the "Benefits of Anæsthesia to Mankind," by Prof. James. E. Garretson, of Philadelphia.

The committee was further instructed to arrange for a banquet to follow the meeting, at which distinguished speakers shall make appropriate addresses; a full report of the celebration, including the papers and addresses, to be printed and issued as a permanent souvenir of the occasion.

Arrangements have been completed to the extent of securing favorable responses from the essayists named, whose papers are now in course of preparation.

The banquet arrangements are also largely completed. To cover the expenses attending the celebration, the fee for admission to the banquet has been placed at $6.00. It is necessary that the committee shall have ample notice of the number who will be in attendance, in order that places may be provided for all who may desire to attend.

Subscriptions will be invited later for the souvenir volume, at a price sufficient to cover the cost of publication.

The celebration will be held in Philadelphia, in Association Hall, Fifteenth and Chestnut Streets, at 2 P.M. on Tuesday, December 11, 1894. The banquet at the Union League at 6:30 P.M.

All are cordially invited to participate in this event, which should enlist the enthusiastic support of every member of our profession.

To that end you are requested to send your check and notify the Chairman of the Anæsthesia Committee at the earliest date possible, in order that an official invitation may be sent to you.

It will be proposed at the meeting that subscriptions be invited for a permanent memorial, to take such shape as the meeting shall decide. (Signed)

ORIGINAL ARTICLES.

THE ETIOLOGY AND TREATMENT OF TUBERCULOSIS OF THE JOINTS.*

WM. M. CUNNINGHAM, A.B., M.D., Bastrop, Texas.

The etiology of tuberculosis is the same whether it invades the lungs or any other part of the body. Ubiquitous death strikes down a large number of its victims with the slow process of tubercular decay. It is considered in almost all cases hereditary. Children of tuberculous parents inherit the diathesis just as their powers of life and slow modes of nutrition are congenital. Yet I have no doubt that hereditary influences have been overrated. The disease is sometimes acquired, and it is a wonder that the cases are not more frequent and the fatality from tuberculosis is not greater, when we consider the infection of our surroundings. The sputa from consumptives, the evacuations from bowel, tubercular inflammations, the secretions from scrofulous affections of the lymphatic glands, the secretions of white-swelling, Pott's disease, caries and lupus. The products of all tubercular decay are carelessly thrown here and there, teeming with tubercle bacilli. These soon dry, are converted into dust, are wafted everywhere by the atmosphere and settle on everything "with its deadly burden."

The tubercle bacillus is a microörganism and loves to settle where nutrition is languid, to develop and propagate its species. There is no organ or part of the human body exempt from its infection, although the lungs seem to be its favorite abode, and in almost all cases where we have cause to attribute the infection to hereditary influences, the lungs and bowels are involved.

Acquired tuberculosis is apt to follow local or general malnutrition, let it be brought about by the traumatism or by an acute or wasting disease or by a long-continued suppuration of any part of the body.

The peculiar habit of the tubercle bacillus is to get into the circulation by way of the skin denuded of its epidermis, by way of the mucous membrane denuded of its epithelium, or wherever there is an asthenic solution of continuity, and, as Dr. Gerster states, "to incorporate itself with a white-blood corpuscle and to influence it in such a manner as to convert it into a lymphoid cell of somewhat large proportions. This cell becomes sessile in some parts of the body." He further says: "After a while new lymphoid cells appear in the vicinity of the first cell, which by this time will have grown to the proportions of a multinuclear giant cell, containing a number of bacilli." And after going through many changes, he states that they result in a "coagulated granular mass. The bacilli contained within them disappear, leaving behind, however, a crop of invisible spores that, transferred to a suitable soil, will readily produce a new growth of bacilli. Soon caseation is established in these coagulated

*Read before the Texas State Medical Association, April 25, 1894.

decayed cell elements. The irritant effects of this cheesy mass on the surrounding tissue stimulated Nature to enucleate it as a foreign substance with an enveloping wall of new-formed tissues.

If this process of enucleation is complete before this infected focus throws out its spores through the lymphatics or veins lying in its vicinity, this infected necrosed mass is walled out as it were from the system. It is encysted. The system is protected from its baneful effects by its encysting membrane, by its caseation and by its non-osmotic action. In this state it gives but little trouble to the system or to the parts in which it is imbedded, not more seemingly than any encysted foreign substance of its size and consistency. This is Nature's method of protection. Now, if Nature is tardy in building this encysting wall, spores of the tubercle bacilli may be carried through the circulation by way of the veins and lymphatics, and possibly by the arterial flow, to invade other parts of the system, and we have a metastasis of the infection—a general irregular distribution of cytoblastions of tubercular infiltration to serve as so many depots for the distribution of these spores in order that they may have a wider field to do their mission, which is to break down the life of tissue wherever they take up their abode. From this source we may have any and all forms of tuberculosis. There is no difference in the gray and yellow, hard and soft tubercle, other than the changes they undergo by reason of age, by evaporation and by the absorption of the coloring matter and liquids of the matter they touch or in which they become infiltrated.

Now to account for tuberculosis of the joints is easy enough. The synovial membrane may become seriously infected with tubercle by way of the circulation from a distant focus, as in cases of pulmonary phthisis. In this case the nutrition of the synovial membrane is at a low ebb. There is no resistance on the part of Nature. Caseation of the lymphoid cell, as soon as it lights upon the synovial membrane, into a harmless mass does not take place. Nature does not encyst it with a protecting wall. It has reached its proper soil. Here it begins to break down nutrition and we have a synovitis and extension of tuberculosis from the lung to the joint. Again, the tubercle bacillus may get into the circulation through some other portal, unite with a white-blood corpuscle, convert it into a lymphoid cell and become deposited in or near the joint as a primary affection. In this case nutrition may be good. The blood as it passes through the capillaries may be rich with a proper pabulum for the tissues to feed upon. There may be a great resistance on the part of Nature. This lymphoid cell of tubercular foci may undergo caseation. Nature may throw up a wall of new-formed tissue all around it to protect the parts in that vicinity from its baneful effect. Here it may remain sessile and apparently harmless. But it is only waiting for a proper opportunity. That opportunity may come with the first traumatism in the neighborhood of the joints. By a blow or sprain nutrition of the parts may be suspended, the encysting wall of this infected foci may be broken down, the sinuses and membranous sheaths of the joints begin to weep. These cheesy foci undergo emulsification, the tubercle bacilli are liberated to begin their deadly work and we have a more extensive tuberculosis of that joint.

Again, an increased exudation of blood serum and of white-blood corpuscles into this enucleated mass of necrosed tissue will dissolve and emulsify this caseous focus, and we have a cold abscess. The tubercle bacilli being liberated, turn their slow but sure forces with an untiring energy against their surrounding wall. In the course of time they break down this wall, and do a more extensive work of destruction in and around the joint. The synovial membrane pours out a greater amount of synovial fluid. The membrane itself soon becomes necrosed. The fluid thickens. Cheesy bodies float about in the fluctuating fluid. The epiphyses of the bones are perforated and they crumble. The cartilages become ulcerated, the denuded bones become necrosed and we have a severe tubercular arthritis. If this process of decay is not stopped here in this joint, the tubercle bacilli will soon increase to too great a number to inhabit this small abode and they will send an army throughout the whole system, and we will have a general tuberculosis; and in the course of time a general cessation of nutrition everywhere and the patient will be in the hands of the undertaker.

The treatment of any disease is always

simplified by a knowledge of the conditions to be met. There is no specific treatment in this disease other than its etiology should be met with a rational treatment. Since anæmia and malnutrition are the doors through which the tubercle bacilli get into the system, strive to build up nutrition by every possible means and endeavor to raise the anæmic to a higher plane of health. Then, whenever possible, lop out of the part or parts by aseptic and antiseptic surgery all traces of tubercle. There may be a dyspepsia to overcome. Anorexia, indigestion and irregularity of the skin, of the kidneys and of the bowels, are frequent concomitants and must be met with a treatment to appease and overcome. The whole system must be as near regulated as is possible. An abundant and rich supply of blood in the system is a prophylactic to the infection of tubercle, as well as it is to any other infection. Then treatment should consist in such measures as will add to the purification and rich quality and quantity of the blood, in order that nutrition of the tissues throughout the system may be promoted and protected.

For this purpose, a good, generous, rich, clean and well-prepared food from which blood can be made stands at the climax of all treatment. Fresh milk from a healthy cow and good bread are an excellent diet in tubercular affections. Cod-liver oil, which I class among the foods, is usually disgusting to the stomach, but combined with malt and other tonics, such as the iodide of iron or some good and palatable elixir, it frequently can be borne by the stomach and answer a good purpose. All tonic remedies are indicated, and we should select from them the tonics which will be best borne by our individual patient and which will be most apt to promote the appetite and digestion and to add to the quality of the blood. Good hygienic laws should be observed as the only mile-posts pointing to health.

Cleanliness of person and place of abode; a cheerful exercise of body and mind in bounds not prostrating; being clothed to best protect the system from the changes of temperature in the climate in which the patient lives; taking plenty of sunlight and fresh air during the day and sleeping in a well-ventilated room at night, are all good laws to observe and need to be pointed out and advised by the physician.

Modern surgery offers much for the alleviation and cure of tuberculosis when affecting accessible joints. The affected tissues or organs must be more or less completely removed under antiseptic precautions to meet the demands of to-day. It does not promise much for tubercular arthritis which is secondary to pulmonary consumption, or where there is a general dissemination of tubercle throughout the system. In these cases nutrition may be improved and life may be prolonged for a while, but ultimately they are all fatal.

But when tuberculous cheesy foci are located in the vicinity of a joint, good results may be expected from a thorough going operation for their complete removal.

If emulsification has taken place in the cheesy foci, aspiration and washing out the cavity with a bichloride of mercury solution (1:1,000) until the fluid returns clear, and repeating the operation as often as the cavity refills, will frequently effect a cure.

When a tuberculosis focus perforates the joint and we have a synovitis and a periarticular abscess, free incision of the abscess, washing out the cavity with the bichloride solution and instituting free drainage, a cure by ankylosis, or probably with some mobility, is possible.

But if there be suppurative infection, widespread and rapid necrosis of the epiphyses of the bones and of the sheaths, tendons and membranes of the joint, the diseased joint or limb must be sacrificed to save the threatened life of the patient. The joint may be removed provided a thorough exsection of all the diseased tissue can be done and the resultnig wound can be healed without suppuration. The infection of any part of the wound with bacteria must be prevented to accomplish a good result. Aseptic and antiseptic treatment, before and during the operation and assiduously applied during the healing process, will often succeed and deserves to be tried before a limb is sacrificed. Exsection of a joint should never be undertaken while there is high systemic fever, or while there is a great degree of heat in the parts, or while the vital powers of the patient are much prostrated.

Free incision into the joint with subsequent drainage and a tonic constitutional treatment should be instituted to pre-

pare the patient for the operation. And only after excessive heat in the diseased joint has been abated and the thermometer under the tongue indicates something near the normal standard of systemic heat should exsection be done.

The joint to be exsected should be washed clean, then with clean and disinfected hands and instruments the operation should be done, while a continuous or frequent irrigation of a germicidal solution (preferably the bichloride solution) is pouring upon the field of operation. The bones should be so divided and brought together in such a manner as will insure the greatest future usefulness of the limb. The retentives should be strong enough and so applied as to hold the parts in a fixed juxtaposition. The drainage-tubes should be disinfected and so placed in the wound as to admit of easy removal and, at the same time, carry off all waste products. The absorbent material should be boiled, then disinfected, and should be in ample quantity and quality to absorb all the secretions of the wound. The bichloride of mercury solution and iodoform or carbolic acid should be used continually; enough to render innocuous all the secretions of the wound and all the dust and filth that may fall upon the dressings from without. The wound should remain in this dressing and under this antiseptic regimen four or five weeks, when the dressings and drainage-tubes may be removed and, if need be, a new dressing applied. But if at any time the dressing should become very much soiled, it should be changed. Or if at any time the patient should have high fever and great pain in the joint, the dressing should be taken off and a search made for the cause, and if necessary a revision of the operation should be done to get rid of any remaining infection which might have been overlooked during the previous operation. If suppuration should occur and there should be much phlegmonous destruction take place in the joint after exsection, the surgeon should lose no time in amputating the limb as far above the infected joint as will be practicable, for on this will depend the slender hope of life.

Exsection is applicable principally to the shoulder, elbow, wrist, hip and knee. In all cases of serious infections of the ankle joint requiring operative procedures, amputation of the leg is probably the best and safest, for the reason that the synovial membrane of this joint is so difficult of complete removal. Rational orthopædic measures of treatment after exsection will encourage a more rapid convalescence and insure greater future usefulness for the limb.

In the treatment of spondylitis, commonly known as Pott's disease of the spine, exsection is not at our command.

Constitutional treatment with free incision and drainage in case of abscess, with antiseptics and such orthopædic appliances as will secure fixation and the greatest support to the spinal column, are perhaps the only means at hand. However, by this treatment many cases of Pott's disease recover.

The Treatment of Biliary Calculi.

M. A. Ranglaret (*Gazette des Hôpitaux*) lays down the following as the main points in the medical treatment of biliary lithiasis:

1. The first is the treatment of the calculus. For this there is no drug that appears to have much influence against the calculus; we are almost powerless.

2. The second point is the state of the hepatic secretion. There is often torpid liver, thick bile, etc. For these conditions we employ the numerous cholagogues with advantage.

3. The third indication in treatment is relief of the pain. Here we employ analgesics and antispasmodics.

4. The last point in the management of these cases is the attention needed for the inflammation and infection. For this employ the antiphlogistics and antiseptics; the local application of neat and counter-irritants are very useful. If the congestion is very intense, put eight or ten leeches on the right hypochondrium, and repeat them if required. For the condition of angiocholitis, where there is infection, fever and chills, the salicylates may be employed. Benzo-naphthol is also good. But the best remedy to combat these symptoms is calomel. It must not be given in too large doses. The author recommends four to seven grains every two or three days.

It is believed by microscopists that the highest powers of their instruments have not yet revealed the most minute forms of animal life.

BRONCHITIS IN TYPHOID FEVER—MALARIA—DIABETIC GANGRENE—TUBERCULOSIS.*

FRANCIS DELAFIELD, M.D., NEW YORK.

BRONCHITIS IN TYPHOID FEVER.

Male, aged twenty-seven years. This patient states that he was in good health until last Sunday, five days ago. On that day he began to suffer from diarrhœa and since that time this looseness of the bowels has continued. The passages at first were large, but latterly they have been smaller. Besides this he has suffered from headache and has been unable to sleep at night. He also has a cough and has raised a little blood. He has had no appetite and has vomited several times. He has felt chilly during a good deal of the time. The man's temperature to-day is 101.5°. The urine is of a specific gravity of 1010; it contains no albumin. The tongue is coated. The pulse is rapid and fairly full; there is no increased tension; it is the rapid and full pulse that goes with a rise of temperature. The heart's action is increased in frequency; there is no murmur. There is impaired pulmonary resonance both above and below the clavicle on both sides, and the breathing is louder on the left side than on the right. There are no rales.

When you look at the man you can see that he is really ill. He has not simply an ordinary cough or an ordinary diarrhœa. The history he gives us is that of beginning typhoid fever, and there are one or two points in connection with it which are worth noticing. Very often at the beginning of typhoid fever there is more or less bronchitis. That is what this man has had and it is apt to lead us astray from the real diagnosis. Still further, in this man there is a change in the resonance over the front of the chest, more marked on the right side than on the left, and there is a difference in the breathing. This may very well mean that there has been an old tubercular change in the upper part of the right lung, with some retraction, but that has no direct bearing on his present condition. During the first few days of typhoid fever the symptoms are very often of such a character that they make you think of other things. I saw yesterday in consultation a patient in the fourteenth day of typhoid fever, and the diagnosis had not been made simply because he had a bronchitis, just as this man had. The symptoms in this case at present are not severe; and, as a matter of fact, the cases of typhoid fever we are seeing this fall in New York are running a pretty mild course. I do not think there are any special indications for treatment in this case. The man should go to bed at once and stay there, because we know very well that the longer a typhoid patient keeps up during the first week of the disease the sicker will he become afterward. It is very well to try to fight off some milder ailments, but with typhoid fever the sooner the patient gives up and goes to bed the better are his chances of early recovery. He should be put on a fluid diet, and for the insomnia I know of nothing better than sulphonal, in twenty-grain doses.

*A lecture delivered at the Vanderbilt Clinic, New York, October 11, 1894.

MALARIA.

Male, aged twenty-nine years; a tailor by occupation. Has been living in New Jersey for the past two years; came to this city on the 3d inst. For three months past he has had chills, fever and sweating, with headache every other day. Since the 6th inst., however, these paroxysms have occurred daily, and instead of coming on at ten o'clock in the morning, as they formerly did, they now come on at eight o'clock. He has no appetite. His pulse is weak and rapid. His bowels are constipated. His temperature now is 102.5°. His urine contains no albumin. His chill this morning lasted four hours. The tongue is slightly coated and moist. The spleen is considerably increased in size and tender.

The history of this patient is a clear one of malarial poisoning. The man states that he has been taking fifteen grains of quinine daily, but instead of growing better, he is growing worse. His paroxysms are coming on every day instead of every other day, and the chills

occur earlier in the day. This is really a much more severe case of intermittent fever than we are apt to meet with in New York City or in its immediate vicinity. Still, there are parts of New Jersey where the malarial fever assumes a pretty bad type, and I have even seen malignant cases there. When we come to the treatment of such a case as this, the first thing I would recommend is that the patient should go to bed. Then as to the feeding. These patients do not have any appetite, and yet, when they are free from the fever, they are capable of digesting food, and you must not allow them to run down too much on a fluid diet; fluid food will answer in some cases, but still patients will not flourish under it, and in these cases you should try to get in a little solid food when you can. Scraped beef is the form of solid food that is most easily digested. You do not want to manage a case like this as you would one of typhoid fever. Another point is that the remedies for the malarial poisoning are more likely to have effect when the bowels are kept open. This should be done not by enemas or suppositories, but by a laxative, and generally speaking one of the salines is best: sulphate of magnesia or Carlsbad salts or the ordinary Seidlitz powders, given about every other day. As regards drugs, I think we can rely upon quinine, even if the patient tells you, as this one does, that he has already taken it and that it has not benefited him. There is a difference in the quality of quinine, and there are different methods of giving it. In a case like this it is best given in solution. You want to get the effect of the drug. The best way is to make up a solution so that each dram of water will contain five grains of sulphate of quinine and five grains of dilute sulphuric acid. I do not think it is worth while to try to disguise the taste of the drug with syrups; it is impossible to disguise it. You commence giving the drug in the afternoon, after his paroxysm has passed off, and give five grains every hour until he has taken thirty grains. This should be repeated the next day, and if after two or three days it becomes evident that he is not improving, I should begin to increase the quinine, if necessary giving him one hundred grains within twenty-four hours, unless poisonous symptoms appear. It is not safe to allow a case of malaria like this to go on without vigorous treatment, as it may readily assume the pernicious form and prove fatal.

DIABETIC GANGRENE.

Female, aged fifty-five. Three years ago began to fail in flesh and strength and to pass her water more frequently, especially at night. These symptoms gradually became worse. Five weeks ago one of her toes became swollen, red and painful. Two weeks later she came here for surgical treatment, and it was found that the affected toe was in a gangrenous condition. Examination of her urine revealed the presence of sugar and she was sent here for medical treatment. During the past week she has been on a diabetic diet, and has received in addition one-quarter grain of codeine, three times daily, with iron and strychnia. To-day her urine is of a specific gravity of 1040, and you can see that there is a large reduction of copper at the bottom of the test-tube, which means that the urine contains a considerable proportion of sugar to the ounce. She has lost flesh and strength. The urine is not very much increased in quantity. As the foot has just been dressed by the surgeon, I will not remove the bandages. The end of the toe is black and shriveled, and just above this there is a line of granulation tissue which is suppurating slightly, and which marks the line of demarcation between the dead and the living tissues. The gangrenous process in these cases usually begins in one toe and then extends to another, or it may extend upward. These patients with diabetes and gangrene are always elderly people. A young person with diabetes does not have gangrene. In some of these patients you first get the history of the diabetes; in others, of the gangrene. Some will tell you that they have been passing too much water, that they have been unnaturally thirsty and that they lost flesh and strength before the appearance of the gangrene; others will tell you that they have been in their natural health, and the first thing they noticed was the onset of the gangrene. In all these cases, however, when you come to examine the urine, you will find that it contains sugar. Still further, you will find that the arteries are tortuous with thickened walls. On account of this chronic endarteritis the arterial supply of

blood is cut off and gangrene is the result. It is not the result of the sugar in the urine, but of the interference with the arterial circulation, and yet there is this curious thing about it, that the sugar is always present. We do not know why this combination should exist. As regards the treatment of these cases, it is equally unsatisfactory for the gangrene and for the diabetes. You can readily see why the gangrene is not likely to do well; the arteries are obstructed and you cannot bring back the blood-supply. The affected tissues are allowed to slough away or they may be removed by the surgeon. I find that some surgeons remove the gangrenous tissues, while others allow them to slough off, and it does not seem to make any difference which plan they pursue. The medical treatment is just as unsatisfactory, because we cannot control the diabetes. These patients continue having sugar in the urine, and I do not think it is wise to try and treat them very vigorously. They should be put on the diabetic diet, but not too strictly; do not starve them. We know that we cannot cure them; they will not live a great while and there is no use in being too strict. The medical treatment amounts to nothing. Codeine is usually advised, and we might as well give that as anything. All we can do is to make these patients as comfortable as possible.

TUBERCULOSIS.

Female, aged sixteen years. This patient, according to her mother, has never been very robust. Last April she had an attack of scarlet fever from which she recovered, but from that time to the present she has been failing. She is losing flesh and strength and is growing paler. She has a cough in the morning without expectoration. She has had no hæmoptyses. Her appetite is fair. Her temperature to-day is 99.8° in the mouth. There is some shortness of breath. On the left side of the chest the resonance, while not a full one, is not much impaired. On the right side, both above and below the clavicle, the sound is shorter, the pitch higher and the quality is different from that on the left side. The quality of the breathing is also changed: the breathing is that of a lung which is partly consolidated. There are no râles on either side. The case seems to be a straightforward one of tubercular inflammation of the upper part of the right lung, which commenced about the time when the girl was recovering from scarlet fever. The girl is very much emaciated, her color is bad, and it must be confessed that the case is not a very promising one. She does not look like a good subject for a tubercular inflammation. She is getting worse rather than better. If her circumstances would allow it, a change of climate might perhaps benefit her, and in her case I would select a warm inland climate. Her circumstances are such, however, that she must stay at home, and the best thing we can do is to try and nourish her as well as possible. I would not advise giving her creasote, or any drugs directed immediately to the lesion in the lung. We can learn from the girl's mother what sort of food she is able to buy, and then make out a diet list, and add to that fat in some form, either cod-liver oil or cream or milk.

How to Arrest a Boil, Carbuncle or Malignant Pustule.

Dr. Barker writes to the *Medical Summary* that he has used the following procedure for several years, with unvarying success. Take a large hypodermic syringe, holding, say, half an ounce, fitted with a small needle. Fill it with a 1 to 500 solutionof mercuric chloride, insert the needle into one of the peripheral openings, in case it is a carbuncle, and wash out the little cavity. Then direct the needle toward and into the surrounding induration and force a little of the solution into it. Treat each opening and its corresponding peripheral circumference in the same manner, carefully washing out the necrosed connective and other tissues that have become separated. Repeat this daily with the solution, gradually reduced to one-half the original strength, until all induration has disappeared and granulations have begun to appear. If the first injection be thoroughly performed, the spread of the carbuncle will be arrested at once, and there will be no more pain. Washing out the little cavities is painless, but the injection into the indurated tissues is not free from pain. The same treatment is applicable to the little furuncles that invade the meatus auditorius externus and the inner surface of the alæ nasi.

INFLAMMATION OF EXTERNAL AUDITORY CANAL FOLLOWING FACIAL ERYSIPELAS.

P. R. CORTELYOU, MARIETTA, GA.

Mrs. C., widow, aged 68, consulted me January 1, 1894, giving the following history: In August, 1893, she was attacked with facial erysipelas on the right side, commencing on under lip and extending entirely over the right side of face, but leaving the left side unaffected. The usual treatment of tincture of chloride of iron internally and tincture iodine and nitrate of silver externally was used by her family physician. The inflammation involved the right ear, which became swollen and, after a week or ten days, began to discharge very offensive matter. This condition was treated with warm carbolized injections and laudanum and olive oil dropped into canal. The inflammation subsided and the discharge from the ear ceased from the latter part of October until the latter part of December. During this time the patient complained of deep-seated pain in the right ear, and intense burning of the side of the face, lower lip and tip of the tongue on same side, the feeling being, as the patient expressed it, as though the parts had been touched with a coal of fire. The face on that side would also become very much flushed. Her physician told her that these symptoms were not caused by the condition of the ear, but were due to the state of her nervous system. Various measures were tried to relieve this intense burning, but all without success, the patient suffering very much from its daily and almost constant occurrence. The discharge from the ear coming on again the latter part of December, 1893, she then consulted me.

On examination I found the lobe of the right ear somewhat swollen and tender, also swelling and tenderness of the tragus and face near it. A thick, heavy discharge from the aural canal, very tenacious, with severe burning pain of the side of the face, lower lip and tip of the tongue on the right side. Hearing distance of watch, "contact." The throat also showed some pharyngitis and post-nasal irritation, and the anterior nasal canal on the right side was congested and irritable. The patient said that often it became completely stopped up, especially at night.

The ear was syringed with warm water, after which a 12-volume solution of peroxide of hydrogen was dropped into the canal, which caused, as the patient expressed it, much frying. The canal was then dried with absorbent cotton. Upon examination with an aural speculum, it was found to be denuded of epithelium in places, especially near the drum membrane. The inflammation showed a condition of acute eczema of the canal. The canal was filled with powdered boric acid. The throat and nasal passages were then sprayed with an alkaline solution and the fluid extract of hydrastis (colorless) applied on cotton. The ear was inflated by Politzer's method and the nasal passages then sprayed with albolene, with 10 drops of eucalyptol to the ounce. Also I ordered Fellows' syrup of hypophosphites combined with Fowler's solution of arsenic three times a day.

The local treatment of the ear and nasal passages was made every other day, and on this line of treatment there was much improvement; the burning of the face, tongue and lip was much less. Hearing distance for the watch increased to four inches. The aural canal not assuming healthy action, I applied nitrate of silver, 20 grains to the ounce, two or three times a week.

The latter part of February, from exposure and cold, the inflammation returned in an acute form, the lobe of the ear becoming much swollen and very tender; also the tragus and the parotid gland became very tender and congested; the pain and burning in the face, lip and tongue were very severe. I ordered syringing with hot water, also slippery elm poultices alternated with a hot salt bag applied to the ear. A four per cent. solution of cocaine was dropped into the canal as needed to relieve the pain, and anodynes were given at night to promote sleep. After a few days there was a free discharge from the inner part of the tragus and also from several points of the canal, with re-

lief of pain and swelling. Again I used the solution of peroxide of hydrogen and, as a dressing, powdered boric acid, alternated with powdered aristol. I gave as a tonic an elixir of three chlorides in place of Fellows' syrup of hypophosphites.

March 19th. The patient began to improve, but the canal still showed a tendency to keep raw and irritable, and was in a condition of chronic eczema. I ordered sulphate of zinc, 15 grains; alcohol, ʒij; aquæ, ℥ij, to be warmed and dropped into the ear several times a day. This change of treatment acted nicely; the swelling disappeared and the canal became more open; the pain and burning were considerably relieved, but did not disappear.

The case is still under treatment, but now with good prospects for recovery. This case to me has been an interesting one, on account of the special symptoms of burning on the side of the face, lip and tongue, and its being confined to the right side, showing some implication of nerves on that side.

COMMUNICATIONS.

DESTRUCTIVE LESIONS IN ACUTE TUBAL INFLAMMATION.*

GEORGE ERETY SHOEMAKER, M.D., PHILADELPHIA, PA.

So much attention has been given to the clinical history and treatment of tubal and ovarian inflammatian that the matter might seem to have been exhausted. Yet cases are not uncommonly appearing where the extensive character of the destructive processes going on has evidently not been realized. It is not every case which tends to recovery on expectant treatment, and it is worth while again and again to call attention to what may occur, if only to induce more men to use eye and hand in diagnosis, instead of relying altogether on clinical history.

So much attention has recently been given to the subject of appendicitis that the rapidity with which its tissue may break down and the surrounding peritoneum be infected is becoming widely understood, and a prompt appeal is now commonly made to physical examination; and in the event of doubt, to the highest court available.

The present object is to present again the fact that inflammation of the tube also may be rapidly destructive, with the formation of pus in quantity great enough to endanger life through softening and rupture of its limiting wall, whether that pus be highly infective or not.

The analogy between the appendix and the tube is not without interest. Both are free in the peritoneal cavity, supported along the edge of a membranous fold; both have muscular, mucous and peritoneal coats.

They are not unlike in size, though varying greatly; while as to situation, the right tube lies very near and often in contact with the appendix, being frequently involved in the same inflammatory process. They are exposed from within to diverse forms of infective bacteria, but either may be infected from the other by continuity after adhesions have formed.

Catarrhal inflammations which do not go on to pus formation or degeneration of tissue occur in both structures, but more frequently in the tube, owing to its greater vicissitudes from situation and function.

The very rapidly progressive inflammations, however, going on to gangrene, rupture and death from peritonitis within three or four days, are relatively common in the appendix and rare in the tube, the destructive process usually taking much longer in the latter case, though everything depends on the character of the infection. A rapidly fatal case with gangrene of the tubal mucous membrane is mentioned by J. Bland Sutton.*

One cause of this difference is mechanical. In the case of the appendix, a hard body, usually fecal, just fills the lumen

* Read before the Philadelphia County Medical Society, October 10, 1894.

* "Diseases of the Ovaries and Fallopian Tubes," p. 236.

before the attack begins. The swelling of the mucous membrane makes the lumen too small for the body inside; pressure results which, aided by the ever-present bacterium, in a few hours causes strangulation and local death. In the tube, on the other hand, there is no foreign body and no local pressure, rupture occurring later at a point gradually thinned by diffused pressure and local degeneration.

Another reason for the relatively greater protection of the general cavity of the peritoneum in the case of the tube is anatomical.

Between its peritoneal covering and the muscular coat is a quantity of loose connective tissue, which, becoming thickened and distended by inflammatory cell infiltration, greatly strengthens the natural barrier against infection from within in the early stages of the disease, and gives time for the formation of adhesions without. In a tube from one of the cases reported this can be well seen. The wall near the uterine end has been cut partly through, and the outer or connective-tissue envelope, about an eighth of an inch in thickness, is peeled back, showing the central rod-like portion undistended and still intact. That portion of the tube is not irretrievably injured in all probability. In some acute cases the same process is seen in the broad ligament which, after all adherent structures are removed, remains half an inch or more in thickness instead of only a line or two. The cellular tissue between the folds of peritoneum has been infiltrated. It has occurred to the writer to observe this condition best marked in subacute cases which have followed puerperal infection. There is a sense then in which what was once called "cellulitis" really occurs, though the ideas of pelvic pathology formerly held have been so largely proved to be erroneous.

Where salpingitis goes on to pus formation, the sequence of events is frequently as follows: The abdominal end of the tube is closed and its cavity distended by retention of the secretion of its walls and by pus formation. The layers of the mesosalpinx are separated until tube and ovary are in contact and adhesion occurs, or else tube and ovary adhere directly without splitting the mesosalpinx. The tube wall thins and the ovary becomes involved secondarily * through a distended ovarian follicle, when tuboövarian abscess results. The ovary now enlarges until its pus contents frequently exceed those of the tube and measure several ounces.

The after-history of these cases, if they escape an early death, is usually made up of progressive invalidism varied by intervals of relief, if by chance the pus empties intermittently into bowel or bladder.

When the abdominal end of the tube does not close quickly enough, peritonitis, which may or may not be limited, is set up by direct escape of fluid from the end of the tube, as in Case II.

Case I.—Tuboövarian abscess; operation; recovery. This illustrates the rapidity with which total destruction of the adnexa may occur, as the gross changes observed had all developed within a known period of eighteen days, or perhaps earlier. I made careful bimanual examination just at the beginning of the attack, and found the pelvic organs practically normal in size, while at the operation each ovarian abscess alone was three inches or more in diameter. The woman was twenty-three years old, married seven years, childless; her second miscarriage, four years before, having been followed by sepsis, which had left her with various pelvic symptoms, but no gross lesions. She was well-nourished, and able to work until an acute attack of pelvic distress brought her to the Methodist Hospital, where she at first entered the surgical service of Dr. H. R. Wharton. When seen by the writer in consultation she presented a flat abdomen, tenderness in a prolapsed left ovary and in the bladder wall, but both tubes and ovaries were normal in size, as was the uterus, which was noted as forward and movable. The general condition was good, and many details of examination, purposely omitted here, were negative. In other words, though she was afterward proved to be on the eve of a violent attack of pelvic inflammation, it had as yet scarcely begun. General treatment was advised, with laxatives and hot douches. She grew rapidly worse, however, in the next ten days, the temperature reaching 104.2°, and exquisite tenderness and tympany supervening.

When examined by Dr. Kynett, under whose care staff changes had now brought her, the uterus had become fixed, and a tender mass had appeared on the right. Eight days later she had been transferred

*Bland Sutton.

to the hands of the writer, and the abdomen was opened. With care and gentleness an attempt was made to separate the adherent coils of intestine from a large mass at the right, but several ounces of thick yellow pus immediately welled from the wound. The sac was evidently on the point of rupture on its upper convexity, where a blackened, sloughing area, an inch in diameter, was about to give way at its center. With some difficulty a tuboovarian abscess was excavated from each side of the pelvis. The lumen of either tube was of the diameter of the thumb, the length increased to about six inches, while the two principal pus sacs, one apparently in each ovary, were three or more inches in diameter. The sac on the left was in the recto-uterine cul-de-sac, and contained highly offensive dark red pus. Being tightly wedged in the depths of the pelvis, held below by firm adhesions, and having a wall much softened and degenerated, this sac also was ruptured in removal. Both tubal and ovarian sacs were completely removed. Because of the black and degenerated appearance of the adhesions which occupied Douglas' pouch, and of the thorough infection of the pelvis by pus distribution during the operation, after flushing and a careful toilet, a gauze handkerchief stuffed with strips of iodoform gauze was packed into this space, and brought out at the lower end of the wound below the glass tube. This gauze was removed on the second day, and stitches, previously put in, tied down as far as the glass tube, after the cavity occupied by the gauze had been cleaned with hydrogen peroxide. For the first two days only there was some vomiting, and liquid food in small quantities was given by the bowel.

Glass tube out on the seventh day. The convalescence, somewhat slower than usual, was complicated by slight superficial suppuration about the drainage-tube end of the wound, so that the patient was not allowed to sit up until the twenty-eighth day instead of on the twenty-first, as is my routine practice. She was discharged well five and a half weeks after the operation. She reports herself well five months later, though with some pain at times.

This specimen, though shrunken by several months' immersion in alcohol, serves to show the condition of the tube and its free communication with the ovarian sac. The point of softening and imminent rupture is seen as a small opening. It would be difficult for me to believe that these extreme changes had occurred so rapidly had I not had an opportunity of mapping out the parts beforehand.

Case II.—Post-puerperal inflammation of both tubes and ovaries, with left pyosalpinx and hematoma of right ovary; operation; recovery and cure. This case illustrates a less advanced condition than the other, pus formation having occurred in one tube only, while different portions of the specimens serve to illustrate steps in the process of destruction.

S. B., aged thirty years; married nine years, three children, three miscarriages. Menses normal until two periods missed four months before. Probable miscarriage two months before applying, with recurrent hemorrhage and several attacks of sharp abdominal pain since, though working as usual. Five days before there was a sharp attack of pelvic pain with fever, which confined patient to bed two days. Examination on admission to the Methodist Hospital showed a subinvoluted uterus, with cervix soft and patulous, with tense fixed tuboövarian masses on each side. There was endometritis, but no physical signs of extra-uterine pregnancy were present, though the history suggested it in many ways.

Cœliotomy was done next day, after first curetting a quantity of soft tissue resembling placental débris from the uterine cavity, which was irrigated thoroughly and packed with iodoform gauze for drainage.

Abdominal incision showed the small intestine and sigmoid flexure moderately adherent to the tuboövarian mass. On the left a small pocket of grayish-red pus, not offensive and not over two drachms in quantity, was disclosed outside the tube and walled in by adherent intestine. This was in all probability the result of leakage of the tube before its outer end was sealed. The ovary was normal in size, inseparably united to the tube, which was hard and contorted, its color very dark red, but nowhere black. The mesosalpinx was not split. The tube was thickened by cell infiltration at the uterine end, gradually enlarging from a diameter of one-half an inch to one inch at the ampulla, which contained reddish-gray pus. Both tubes

were sealed and their fimbriæ lost in adhesions. Both broad ligaments were infiltrated to a thickness of half an inch. The right tube was shorter and smaller than the left, but though firmly buried in strong adhesions it contained no pus. It was very hard. The right ovary contained a hematoma about two inches in diameter, the blood being black and semifluid. Total removal of tubes and ovaries; flushing; glass drainage; good recovery. The woman was seen well and working five months later, complaining only of the flushing due to artificial menopause.

The specimen here shown exhibits in its different parts stages in the progress of salpingitis. Near the uterine end of one tube which has been split may be seen the greatly swollen longitudinal folds of mucous membrane not yet adherent together. Mucous surfaces do not adhere, when inflamed, as early as do serous surfaces. These folds, when swollen, very tightly fill the tube, so that it feels hard, and when it is cut longitudinal they appear to have been inclosed in a space too small for them, so that the incision will not close again. Farther out in the dilated ampulla pus was found, and the structures are extensively altered in appearance. The fimbriated end had been sealed by covering in the fimbriæ and packing them together inside the tube, the serous covering swelling and uniting outside them. Though they are somewhat adherent together they still can be distinguished. Later on in the disease they would become disorganized or lost in the wall of what had become simply a pus sac with smooth rounded end.

EXHIBITION OF CASES ILLUSTRATING THE OPERATIVE TREATMENT OF ILIAC (SPINAL) ABSCESSES.*

JAMES K. YOUNG, M.D., PHILADELPHIA.

These cases illustrate the operative treatment of iliac abscesses of spinal origin.

CASE I.—Martin W., white, male, aged four years.

Family history: Negative.

Past history: Natural birth. At ten months, croup. At four years, brought to University Hospital Dispensary, having suffered for six weeks with pain in left thigh. During this period he has had a limp, and has been supposed to have had rheumatism. He has had night cries.

Mensuration showed:

Length—R. L. 18″ Circ. @ 3″ = 9½ @ 5″ —10¾. R. calf = 7⅜″.

Length—L. L. 17¾″ @ 3″ = 9½ @ 5 — 10¾. L. calf = 7⅜″.

Diagnosis at this time was doubtful, the psoas irritation resembling incipient coxalgia. Later, lumbar Potts was indicated by the characteristic posterior deformity.

At five years of age, in January, 1894, had chicken-pox and "grippe." At this period the kyphosis was slowly enlarging. The child had been wearing a Taylor spinal brace for four months. The brace being out of order, the child was put to bed at the end of January, 1894. The day after removal of the brace a tumor appeared in the left groin.

February 5, 1894. Admitted University Hospital. Examination shows the tumor in the left groin to be above Poupart's ligament just internal to the anterior superior spinous process of the ilium. It is a fluctuating swelling, easily distinguishable from a hernia, to which it has a superficial resemblance. The patient's back shows a slight kyphosis involving the second and third lumbar spines.

Diagnosis: Pott's disease with slight kyphosis, and coexistent with ilio-lumbar abscesses. Operation by Dr. De Forest Willard on day of admission. Ether anæsthesia. Abscess cautiously opened; much pus evacuated. Counter-opening made in back, and rubber drainage passed through.

9th. Discharging freely.

10th. Temperature 102⅘°. Enema followed by drop in temperature.

22d. Temperature still hectic. Sinus washed out with peroxide of hydrogen and sublimate solution.

24th. Onset of measles. Isolation.

March 16th. Out of quarantine.

29th. Plaster jacket. Discharge has lessened.

*Read before the Philadelphia County Medical Society, October 10, 1894.

April 20th. Back and groin healed; is up in chair.

May 16th. Cast removed; brace applied; child walks.

23d. Discharged, well.

CASE II.—Raymond C., aged four years; American.

Family history: Maternal grandfather died of phthisis.

Past history: First symptom noted by mother in April, 1893; child waking screaming and rigid at night. Three weeks later a severe chill, accompanied by muscular spasm.

Previous treatment, the application of a liniment advised by a physician.

Examination shows marked lordosis.

Treatment: The application of a Taylor brace, and syr. hypophosph. simp. drachm j., t. i. d.

Diagnosis: Lumbar Pott's disease.

Present history: Admitted to University Hospital, July 15, 1894. Patient complains of pain in sitting posture. The spine is still arched. There is distinct fluctuation in left iliac region, which is slightly prominent and may be said to be pointing just above Poupart's ligament. This abscess is probably of vertebral origin.

Operation: Operation by Dr. James K. Young, July 20, 1894. Incision in line with Poupart's ligament, along its outer third. Pus evacuated. Counter-opening a little above sacro-iliac junction. Antiseptic precautions; iodoform dressings.

For these notes I am indebted to Dr. Jos. M. Spellissy, assistant surgeon in the Orthopedic Dispensary.

I had intended reporting a similar case which occurred in private practice, in which Dr. Willard, Dr. Ashhurst, and myself were associated. In this case it was considered advisable to either trephine the upper part of the crest of the ilium or remove a portion with a rongeur forceps, so as to permit the drainage-tube to lay flat in the iliac fossa. The latter was done, and appeared to facilitate the drainage and healing of the abscesses rather than retard them.

The frequency of these abscesses is well shown in Michel's statistics, in which out of forty-eight abscesses of spinal origin, thirty-nine, or 70 per cent., were in the pelvis.

In regard to the treatment, the opinions of authorities range from extreme expectancy to early and radical operation.

Two plans of treatment are offered: that of expectancy and that of incision and drainage. Cases are recorded in which, under expectancy, recovery has ensued; notably one each of Drs. Taylor, Bradford and Lovett, and I have one now under observation in which absorption appears to have occurred.

There are two other methods to which attention must be called:

1. Repeated aspiration.

2. Injection of fluids to promote absorption.

The former is unsatisfactory on account of non-withdrawal of caseous clots, and the latter dangerous, and in some cases fatal, from absorption of carbolic acid. The objections to the early radical operations, especially erosion of vertebræ, is the high mortality, and Dr. Rupprecht, of Dresden, informed me six years ago that after a fair trial he had abandoned the radical operations, because 50 per cent. died from the operation. The operation here advocated is performed under strict antiseptic precautions. The abscess is opened by careful dissection, it is thoroughly irrigated with boiled water and boric acid solution, a long, grooved director is passed up to a point above the sacro-iliac juncture, and a straight longitudinal incision is made upon it. A rubber tube is passed through and secured with safety pins.

Emulsion of iodoform (10 per cent.) ℥ss is thrown in, iodoform gauze packed about the wound, and a bichloride dressing applied.

Indications: The indications for the operation are: (1) where the abscess is large and making pressure upon important organs; (2) where the abscess is increasing rapidly in size; (3) where there is danger of rupture of the abscess into the peritoneal cavity.

VOLUNTARY muscles are almost always red; involuntary muscles are generally white, the most notable exception in the latter case being the heart.

THE blood flows almost as freely through the bones as through the flesh of very young children, but as age comes on the blood-vessels in the bones are almost filled with matter.

ILIAC ABSCESSES, NON-SPINAL IN ORIGIN.*

DEFOREST WILLARD, M.D., PHILADELPHIA.

Iliac abscesses arising from causes other than spinal caries are not infrequent. Accumulations of pus in this region should receive careful attention, as the prognosis will be greatly influenced by the source of trouble. I have seen a considerable number of these pus accumulations either from direct or indirect violence. In several instances the individual has been conscious of a sudden pain or "giving way" within the pelvis during violent exertion or sudden wrench of the body, or from other peculiar movements. This is usually followed by pain or discomfort. In two or three of my cases the pain has lasted for months, and in one instance for a year, before any positive results were discoverable. In the majority of cases a rupture of some fibers of the iliacus probably takes place, suppuration follows, and the pus slowly makes its way downward toward Poupart's ligament.

There is usually slight flexion of the leg, or at least an inclination to relieve the pain by relaxation of the tense sheath.

At the present day it is well to remember that an individual may have pain and inflammation even in the right iliac region without having appendicitis, and that a woman may have a pelvic abscess which is not due to tubal disease.

One case I recall where a man had suffered for months and had become greatly emaciated and exhausted, presenting the appearance of tubercular disease, yet was speedily and thoroughly cured by through-and-through drainage of a pus cavity in this region.

In another case the condition found was apparently due to degeneration of the tisues from an attack of the grip. The patient was not conscious of any injury having been received in this region, yet there was a possible history of rupture of some of the fibers of the iliacus several months previous to an attack of influenza. When seen he had high temperature, chills, perspiration, etc., and had been in bed many weeks, suffering intensely with pain down the leg and in the hip. The hip was partially flexed and adducted, but there was no thickening about the trochanter or hip-joint. The left iliac fossa was firm and dense, and a large tumor presented under Poupart's ligament extending down the vessels.

Two quarts of pus were evacuated through an incision just below the anterior spinous process, and a tube was carried back to a counter opening made above the crest of the ilium. No bare bone was discoverable, and all the symptoms of hip disease were speedily relieved. There was absence of evidence of spinal caries.

In another case the mass was at first believed to have originated from an appendicitis, but this supposition was afterward proven to be unfounded.

In another instance there was deep-seated pain, emaciation, and so forth, indicating malignant disease. An incision was decided upon with the result of obtaining a large amount of pus; successful recovery ensued. In this case there was absence of all evidence of bone disease, and the result justified the diagnosis.

The conditions with which these abscesses are most liable to be confounded are abscess from spinal caries, from hip disease, and from innominate disease. I have seen a number of cases of the latter complaint, where the caries has been situated upon the inner side of the innominate bone, and in one instance the ostitis was at the internal face of the sacro iliac junction.

It is frequently difficult to decide in a case of bared iliac bone whether the bone lesion was primary or whether it is a secondary result from maceration in the pus.

A careful history of each case is requisite in arriving at a conclusion, and in some instances a diagnosis is only possible after an incision. In spinal caries there will necessarily be rigidity of the back, but not necessarily pain nor even deformity. If there is vertebral ostitis there will usually be a history of "stiff back." Of course, if kyphosis is present, the diagnosis is easy.

A diagnosis from abscess from hip disease which has perforated the acetabulum is not always easy. There may be flexion of the hip; there may be adduction or ab-

*Read before the Philadelphia County Medical Society, October 10, 1894.

duction, and there will necessarily be rigidity with fixation, especially if tension be put on the iliac muscle. To make a correct diagnosis requires close attention to the whole group of symptoms. If a surgeon considers a single symptom rather than the group he will find it easy to confound these abscesses with any one of the conditions already mentioned.

I have seen a number of cases of sarcoma in this region (*Med. and Surg. Rep.*, 1894), and in the early stage I do not believe that it is possible for any one to arrive at a positive diagnosis. The history may throw some light upon the subject; but as many sarcomas are lighted into discoverable existence by injury, even this is of but little service.

THE DOCTOR'S WIFE—AN IMPORTANT FACTOR IN HIS SUCCESS OR FAILURE.

Much has been said of the trials of the doctor's wife. Complaint is often made because the doctor leaves his wife so much alone; because he does not go with her to parties, to the theater, or pleasure-driving; does not spend many evenings reading to her from some entertaining book; is not always bubbling over with animal spirits after the performance of his daily tasks, etc.

We have observed that he who has such a wife, or one not content to share the life of the busy doctor, is doomed to failure more or less complete. On the other hand, when the doctor's wife takes a pride in her husband's work, enters into his life, is proud of his success and sympathetic with his failures, then the doctor succeeds.

Dr. E. C. Valentine (*Medical Record*) tells the following illustrative of many points in the success of the doctor and his wife. He says: "Once I had occasion to call on a successful practitioner, whose home life, because of its happiness, was the subject of much comment. The doctor was not at home. His wife urged me to wait for the doctor, as she had sent for him a moment before. I explained that I was not a patient but a colleague. 'I am so glad, doctor,' she responded; 'won't you come in quickly, please? I have a man on the operating-table with, I think, his posterior tibial artery cut. I controlled the hemorrhage with an improvised tourniquet, but of course would not attempt to ligate.' I then observed that Mrs. Doctor had stained her elegant dress with blood. Her hat and gloves were lying on the floor of the operating-room. The patient was lying with his injured leg raised on an inverted chair, the trousers and drawers slit, and a tourniquet neatly applied to control the bleeding. Just then the husband came in. She assisted him at the ligation; pride in her husbandand in herself gleamed in her eyes, and when all was done she patted him affectionately on the cheek and said, 'Good-by, darling.' 'But, dearest,' he said, 'you have lost the matinée in consequence, and your new dress is ruined.' 'What is a matinée or a new dress to seeing a good operation performed by a good surgeon, and that surgeon my husband?'"

Dr. Valentine remarks: "This woman was proud to possess her husband; she sought happiness in being his wife, and did not complain because the world called her the wife of Dr. ——. Is it a wonder that such a man succeeds? He leaves home with encouragement from her; he hurries home when tired, exhausted, in doubt, to get more encouragement and stimulus for study and work from her; she is all and everything to him; both are happy, and she consequently does not fly into print to proclaim what a miserable creature she is."

With shadings to suit each individual case, this story is typical of the true wife —the true doctor's wife. Such a wife is a priceless life-partner to the doctor.—*American Lancet.*

Acne.

To cure acne, give one-fiftieth grain of sulphide arsenic, three times a day, and apply first sulphuric ether to the pimples and face, wash well with fine soap and apply topically a saturated solution of boracic acid in alcohol. The cure is expedited by wearing at night a mask made of thin rubber, such as dentists use, and is called rubber dam.

EDITORIAL.

THE METRIC SYSTEM.

For a year or more this much-mooted subject has enjoyed a rest, which we propose to disturb by again bringing it to the attention of our readers. At one time and another, probably all the arguments for and against the change to metric units have been presented. Yet the whole literature of the subject may be condensed into the statement that one set of physicians believe that the conceded difficulties of making the change will be more than compensated for by the advantages of the decimal system, while another set, though granting these theoretical advantages, believe that the trouble of learning and the danger of using unfamiliar concepts of quantity are too great to warrant the reform. Such an argument has doubtless been held over every radical change in human customs. The argument may be shortened under a paternal government and lengthened in a country where an atmosphere of liberty strengthens personal opinions and prejudices, but in the long run genuine superiority will be recognized, while the specious success of false reforms will prove temporary. It is not difficult to prophesy the outcome of the present controversy. With the exception of the British empire, which is always conservative, and of the United States, which is usually radical but always independent, the metric system is in practical every-day use in the entire civilized world, while in nearly all branches of science it is almost universally employed. The first timid footsteps into an unknown region may be retraced; not so the onward march of multitudes.

The latest decisive battle for the supremacy of the metric system in the medical domain was that fought for the possession of the United States Pharmacopœia. In 1880 a foothold was obtained, but it was precarious. In 1890 it was questionable whether this would be permanently lost or whether a decisive victory would be gained. The superiority of a scale of denominate units in accord with the universally employed decimal notation of abstract numbers once more prevailed. But though the victory was won, the majority

of the defeated are still to be "reconstructed." It would be not only discourteous, but unwise and dangerous, to insist on the abandonment of measures familiarized by long use. The middle-aged and elderly members of the profession will, for the most part, adhere to the apothecary's system. The change, however advantageous theoretically, can offer to them no adequate compensation for the trouble involved. It is the comparatively young men who will receive the benefit, those who still build up their prescriptions, ingredient by ingredient, by the tedious process of multiplication of the single dose, not those who have in mind in an instant the completed prescription.

There are certain obvious duties in the matter to which we wish to call attention. The pharmacist, whether he has a store in the heart of a populous city or whether he is located at some country corners, is just as much under obligations to be able to compound a metric prescription as he is to keep in stock an officinal drug. He has no more excuse for being without metric weights and a cubic-centimeter graduate than without laudanum and bismuth. Furthermore, it is the duty of every official pharmaceutical and medical society, without reference to individual opinions, to exercise whatever power or influence it may have to compel adequate provision for compounding prescriptions by either the customary or the official method.

We have for several years made personal inquiry as to the equipment of any drug store to which our prescriptions might probably be taken, and, so far as possible, have not allowed them to be compounded in stores which were improperly equipped either in measures or drugs or at which a conspicuously irregular trade was carried on. Doubtless there is truth in the argument which some physicians have advanced that druggists thus treated will not send patients to us, but our personal relations with reputable pharmacists have been uniformly pleasant, and we doubt whether the man who caters too much to others is the permanent gainer thereby.

Students have often said: "I believe in the metric system, and when I get out of college I am going to learn to use it, but here I am taught in the old way, and I must know that anyhow." The representatives of the medical profession have formally adopted the metric system, not for the benefit of old practitioners, but for the sake of those who may enjoy the advantages of the new without the trouble of unlearning the old. The family physician may write his prescriptions as he pleases, and no one is the wiser except the druggist who compounds them; but the man who accepts the privileges of a professor should realize his responsibilities also. His students should have the benefit of everything that is new and good. Directly or indirectly they pay their teachers for being abreast of the times, and they are defrauded to just the extent that the latter allow the inertia of habit to carry them by their duties to the present and future.

Bits of Natural History.

In old age the height of man diminishes.

The skin is the only part of the human body that is not hardened by age.

The tail of a beaver is a regular trowel and is used as such.

Carnivorous animals seldom produce more than two young at a birth.

The flesh of the boa constrictor is eaten by the aborigines of Brazil.

The bones of very aged persons are said to have a greater proportion of lime than those of young people.

The lowest order of animal life is found in the microscopic jelly-fish. It is simply a minute drop of gelatinous matter.

The Call of Duty.

Friend—Your husband seems ill.

The Minister's Wife—He is overworked but he will take no rest. Three nights last week he insisted on going to see those hateful living pictures in order to more effectively denounce them from the pulpit.—*Puck.*

THE PREVENTION OF DIPHTHERIA.

The following is furnished for publication by the New York Health Department:

NEW YORK, Sept. 28, 1894.

CHAS. F. ROBERTS, M.D., Sanitary Superintendent—

Sir: We desire to direct the attention of the Board of Health to the necessity for the adoption of some more adequate means to prevent the extension of contagious diseases in tenement houses and apartment houses, and particularly for the enforcement of isolation of persons sick with these diseases. The methods which have been long employed in the Health Department, *i.e.*, frequent visitation and instruction by Department Inspectors, have been found to be only partially effective. It has been the custom for years, in cases of contagious diseases, for the Inspectors of the Department to visit the families of the sick persons, inform them as to measures of disinfection and methods of isolation, and at the same time to notify other families in the house of the existence of a case of contagious disease in a given apartment. This method of giving publicity to the case and of warning other occupants of the house is ineffective in the accomplishment of the desired end; *i.e.*, the complete isolation of the patient and the prevention of further infection. Notifying all the inmates of a large tenement is a very difficult matter, and, if notified, experience has shown that they soon forget the existence of illness in the house. Repeated inquiries have demonstrated the fact that frequently many of the inmates of the house where there is a case of contagious disease do not know of the existence of any sickness.

Further than this, this method fails entirely to protect strangers or visitors who may go to the house or apartment. Ladies in search of servants have been repeatedly found in houses or in apartments where cases of contagious disease were present, and servants who have been living with families where there are cases of contagious disease, on obtaining situations frequently go to their employer's house carrying infection with them; or, when relieved from duty for an afternoon or evening, visit where there are cases of contagious disease and not infrequently carry infection back to the houses in which they are employed. Very commonly, washing or various kinds of sewing is secretly done by other members of the family in apartments where such cases are ill, and the garments thus infected on the premises are later returned to the owners. In small shops, business is sometimes carried on, and in one of several instances recently, a number of cases of diphtheria were directly traced to an infected candy store.

Notifying inmates of the house is ineffectual, further, because it has been found that, as a rule, intercourse of families in tenement houses is not with others in the same house, but with families who live in other houses, and the latter are entirely unprotected by the methods at present followed.

It has seemed to us, after careful consideration of this subject, that the desired object would be best obtained by the placarding of apartments in tenement houses where cases of contagious disease exist, and we therefore have the honor to recommend that hereafter the Chief Inspector of Contagious Diseases be authorized, in his discretion, to placard apartments in tenement houses where there are cases of contagious disease. The following considerations may render more apparent the necessity for this action:

1. Under the present conditions it is impossible to prevent strangers and visitors from entering apartments where there are cases of contagious disease, and they or their clothing thus frequently become infected, and either they contract the disease themselves or they transmit it to others. These strangers or visitors are usually not aware of the existence of disease in the house or apartment, and unwittingly expose themselves and act as media for the dissemination of the disease. If apartments were placarded, this means of dissemination would be prevented.

2. In diphtheria, as has been repeatedly and abundantly shown by the investigations of this Department, patients are often apparently well long before they are free from the infectious agents, and in spite of repeated warning from Department Inspectors these patients, especially when children, mingle with other children and thus transmit the disease to

them. This is one of the most common and important means for the dissemination of diphtheria, and it is of no less importance in scarlet fever and measles, as in the latter diseases desquamation frequently continues many days after the patient has apparently quite recovered.

3. There are at present no means by which other inmates in tenement houses can know when convalescent cases of contagious disease have ceased to be dangerous. They can only be governed by appearances, which, as we have seen, are deceptive. If apartments where cases of contagious disease existed were placarded, isolation would be enforced by the other occupants of the house until the Department Inspectors allowed the placards to be removed.

4. The moral influence of such placards, both upon the inmates of the apartments, the inmates of the house and strangers or visitors to the house, would be of as great service in enforcing isolation and preventing extension of disease as the visits and instruction of our inspectors. It has been found impossible, even where daily visits were made by medical inspectors, assisted by the Sanitary Police, to enforce the isolation of children convalescing from diphtheria and scarlet fever after the serious symptoms have disappeared. It is undesirable at such times, unless absolutely required, to remove such patients to the hospital, and yet in the eruptive fevers this is the period of the disease when there is greatest danger of transmission to others.

During the last year we have had a serious epidemic of diphtheria to deal with. The number of cases reported weekly during the last months, however, has steadily decreased. The schools have just now opened, and it seems to us that the most strenuous efforts should be made to prevent a new outbreak of the disease or its reintroduction to the schools. This measure would be of undoubted service in accomplishing the desired object.

We would recommend, however, that placards should be nailed to the outside doors of the apartments in which cases of contagious disease are present, when in the judgment of the Chief Inspector of Contagious Diseases this course seems to be desirable, and that the placards should bear the following inscription, differing as to the name of disease in question and as to color. The color for diphtheria should be white; for scarlet fever, red; for measles, blue.

"DIPHTHERIA.

"All persons not occupants of this apartment are notified of the presence of diphtheria in it, and are warned to avoid entering it until this notice is removed. The persons sick with diphtheria must not leave as long as this notice remains here.

"The removal or defacement of this notice is forbidden.

"By order of the Board of Health.

"——— ———, President.

"——— ———, Secretary."

For some months in certain classes of tuberculosis the system of placarding apartments has been authorized and employed by the Health Department, and has proven very satisfactory in the attainment of the object desired. The only objection apparently to be urged against this measure is that the inmates of the apartment may object to the publicity thus entailed. This, however, is exactly the object which the measure is justly and properly designed to subserve, and is, in our opinion, the strongest argument in favor of its adoption. Respectfully submitted,

(Signed) HERMANN M. BIGGS,
Pathologist and Director of the Bacteriological Laboratory.

A. H. DOTY,
Chief Inspector of Contagious Diseases.

The above report was approved by the Board of Health Department of the City of New York at a meeting held on September 28, 1894.

(Signed) EMMONS CLARK,
Secretary.

Alcohol.

The lamp wick does not burn so long as there is oil on it. As the oxygen which reaches the wick is not sufficient to burn both the oil and the wick, the oil, being most inflammable, is burned, leaving the wick merely charred. So if some highly oxidizable substance, as alcoholic drink, is taken into the system, it will be oxidized first, leaving the proper food elements of the body only "charred," or incompletely oxidized.

IN the treatment of alcoholic habits, don't forget the necessity for excessive nutrition of some kind easily appropriated.

ABSTRACTS.

TUBERCULOUS CATTLE.

A dispatch from Washington is to the effect that as soon as the appropriation of $100,000 in the agricultural bill becomes available, the Bureau of Animal Industry of the Agricultural Department will begin an investigation of the prevalence of tuberculosis among cattle. The investigation will be commenced among herds from which Washington itself gets its supply of milk. Various herds in that section of the country have been inspected and tested from time to time with startling results. A herd ten days ago on a farm in the District was found to have 80 per cent. of its animals infected; and a few days before that no fewer than 90 animals in a herd numbering 125 near Richmond, Va., were discovered to be diseased. These are extreme and unusual cases, it is true; but occurring synchronously within a narrow radius, they were enough to rouse the Government to a sense of the danger to which the country is exposed from this source. An experiment performed by one of the scientists attached to the animal industry laboratory about the same time tended in the same direction of alarm. Ascertaining from test experiments which he had been making with the milk supply of the capital that it was tainted with tubercle, though perhaps not tainted sufficiently to be very dangerous to human health, he inoculated a guinea-pig with the milk; and, sure enough, after a few days, when the tubercle bacilli contained in the milk had had time to plant themselves and develop in his system, the rodent exhibited unmistakable tuberculosis. Concurrent circumstances like these, forced on the attention of the Government, produced the belief that it was about time a general investigation of diseased cattle should be made, if the danger to human health so portended would be avoided.

The way in which cattle are diagnosed most easily and most surely for tuberculosis is by the inoculation of them with an infinitesimal quantity of a preparation of which we heard much more a few years ago than we hear now—Koch's tuberculin. Tuberculin is a pretty expensive drug, costing $8 for about a teaspoonful. The Government prepares considerable quantities of it and distributes it free among State boards of health and live-stock commissioners. Inoculated with tuberculin, cattle straightway declare whether they are infected with tubercle or not, by the reaction that follows or fails to follow the inoculation. Now tuberculin has been furnished to twenty-three of the forty-four States of the Union, and the tests which have been returned to the Government from these States, although they have not nearly all been returned yet, show conclusively that the disease is spread among cattle throughout almost the entire Union. In fact, the probabilities are that it will be found that 5 per cent. of all the cattle in the United States are suffering more or less with tuberculosis!

That is the alarming state of things of which the Government will have to take account, and for which it will some way or other have to devise a remedy. It cost $1,500,000 to eradicate contagious pleuro-pneumonia from United States herds, and the amount of contagious pleuro-pneumonia was not a tithe of the amount of tuberculosis which at present exists. So many milch kine alone are infected with it, says Dr. Salmon, of the Bureau of Animal Industry, that if they be all killed "fresh milk will cost as much as champagne." It woulk be well for us not to forget that of all our cattle, and especially of all our milk-givers, at least 5 in every 100 are infected with tuberculosis; which disease, appearing most commonly as consumption in the human subject, is easily communicable both through meat and through milk. Common prudence would suggest the necessity, therefore, of boiling all milk before it is administered to anybody.—*Public Opinion.*

Bed-Sores.—Bed-sores may often be aborted if, as soon as the skin becomes red, a solution of the nitrate of silver, of the strength of twenty grains to the ounce, is applied locally to the parts; but this will not be effective in cases of paralysis.

SOCIETY REPORTS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of October 10, 1894.

Dr. G. E. Shoemaker read a paper entitled

DESTRUCTIVE LESIONS IN ACUTE TUBAL INFLAMMATION.

(See page 645.)

DISCUSSION.

DR. M. PRICE: I have been much pleased with the report and with the success of both operations. I think that I cannot exactly agree with the doctor in considering a case of eighteen days' duration as altogether acute. Many of these cases go on to a fatal termination before going to such a length of time. I have seen cases of gonorrhœal salpingitis where the gonorrhœa had existed only a few weeks, and the ovarian and tubal trouble only a few days, when the tube was removed with pus pouring from its end. The gonococcus would probably have been found in great numbers if it had been looked for. In this case there was a general peritonitis with inflammatory lymph covering the intestines in twenty-four to thirty-six hours. I remember three cases of forcible dilatation where general peritonitis with pus pouring from the tubes at time of operation existed eight days after dilatation. I believe that many of these cases which ended fatally are considered to be cases of appendicitis. I have also found many of these cases of pelvic trouble complicated with appendicitis. A few months ago I operated on a woman who had for years suffered with so-called appendix trouble. The principal evidence in favor of this was the position of the woman, who bent over to the crippled side with her hand in that position. At the operation the tube was found fused to the ovary. It is often impossible to say in these cases whether the primary disease was in the appendix or in the tube. In these cases recovery is rapid because the patient has been prepared for a certain amount of suffering, and the peritoneum has been educated, as it were, to bear almost anything.

The only thing that I can criticise, and I can do that conscientiously, is the use of gauze drainage. If glass drainage alone had been used it could have been removed at the end of thirty-six hours. There is always sloughing and dirt following gauze drainage. While I use it in abscesses where the peritoneum has not been opened, I insist on its removal at the end of twenty-four hours, and its reapplication. Where gauze packing is used within the peritoneum the membrane is exposed to injury, and the viscera are wounded in its removal, as it adheres to everything, and its removal requires considerable force, unless it is left for a long time. With gauze drainage you run fifty per cent. more risk of death than if glass drainage alone has been used.

Dr. Senn has recently asserted that glass drainage causes fecal fistulæ. I can select the cases that are going to have a fistula. At time of operation in cases of abscess of the ovary or tube allowed to run on for a long time, with several attacks of pelvic inflammatory trouble, you will often find a necrotic bowel requiring the use of the Murphy button for resection. If glass drainage is used with care and the tube properly placed, the chance of avoiding a fecal fistula is very good, and the patient is safe. In a case operated on during the past year I was sure that there would be an injury to the bowel, for the abscess on the left side had several times discharged through the bowel, and I knew that there was a sinus or such adhesions as would necessitate wounding the rectum. In this case a drainage-tube was placed in the left cul-de-sac, and within forty-eight hours feces poured out by the tablespoonful. That case went on as nicely as could be, and recovered. I could point out four or five cases in the past year where before the operation was completed we had every reason to expect fecal fistulæ, and in every case recovery occurred without difficulty.

Where feces is discharged through the drainage-tube a little different treatment is required. The tube should be left

until you are sure that the drainage tract has been mapped off from the general peritoneal cavity. The treatment of this drainage tract is a matter for consideration. It should not be touched with a syringe, or any attempt made to clean it below the skin. If you do you will have complications and injury to surrounding viscera, giving a fistula which is incurable. All these cases should get well, and the charge that the drainage-tube is responsible for fecal fistulæ, I think, is a great mistake. I have seen thirty fecal fistulæ, and every one has healed under the treatment mentioned.

Dr. G. G. Davis: My observation does not correspond with that of Dr. Price, that fecal fistulæ always heal. I have seen several fecal fistulæ the result of abdominal operations that have not gotten well. I cannot see why the simple cleansing of a fecal fistula should retard its healing, and I do not believe that it does. Dr. Price's objection to the use of the syringe may be a good one if the nozzle of the syringe is long and it is thrust in deeply and sufficient manipulation made to materially disturb the parts; but that would be followed by hemorrhage, and I think that no one in cleansing the parts would use such violence. If all the cases that Dr. Price has seen recover, his sources of information must be more limited than mine have been.

Dr. Price: Dr. Davis states that he has seen cases that did not get well, and he admits that the syringe was used, and this was a good reason for the failure to close. Every fistula which is syringed does badly. The kind of fistulæ that do not get well are those due to tuberculosis. There is also another class that do not close, and that is those where there are sloughs of the bowel from injury, and the bowel is in close contact with the skin, and there is no intervening tissue which can bridge over the opening. These will not heal without operation, but deep fistulæ, not tubercular and where the lumen of the bowel is sufficiently large, always recover.

Dr. James M. Brown: I was much interested in Dr. Shoemaker's allusion to the relation between appendicitis and ovarian and tubal trouble. Two cases of appendicitis, among several that I have had in the past year, I believe to be the result of primary pelvic trouble, probably ovarian trouble. In both of these cases operation proved the presence of appendicitis. The point I wish to make is that in these cases the probable cause was primarily some pelvic inflammatory trouble. A third case still under observation had recurrent attacks of appendicitis with each menstrual epoch for a number of months. Then the attacks became more frequent and occurred between the menstrual periods. For the past two months there have been no attacks. I grant that it requires some care to distinguish a condition of this kind occurring in connection with the menstrual epoch, but I think that the diagnosis has been positively made, and if there is recurrence of the attacks operation for removal of the appendix will be done.

Dr. H. A. Slocum: I would ask Dr. Shoemaker if he has determined the cause of the rapid change in the case reported; whether it was due to the condition of the patient or to some particularly malignant germ. The history of the first case emphasizes the necessity of taking special care in the treatment of cases of miscarriage, and, if possible, to thoroughly cleanse the uterus and thus prevent troubles which may follow long afterward.

Dr. Shoemaker: In reply to Dr. Slocum I would say that the rapid growth of the abscess is not without its analogy in other parts of the body where there is no dense fascia, and where the tissues involved are only connective, muscular or glandular. We have the rapid formation of large abscesses, the material in which comes from the degeneration of the cell infiltration after inflammation.

The question of the use of gauze drainage in tubal and ovarian inflammatory troubles does not often come up in operations, as total removal and careful toilet usually suffice. In this case the adhesions looked so black that I hesitated to trust glass drainage alone, and the result made me satisfied with what was done. I do not recall that I have had to use gauze drainage in a tubal or ovarian pus case before, and I hope never to do it again; but we all know by experience its value in some forms of appendicitis. If a handkerchief of gauze is used, with a ligature attached to its center inside, and this is stuffed with strips, the removal is facilitated.

Dr. James K. Young gave an

EXHIBITION OF CASES ILLUSTRATING THE OPERATIVE TREATMENT OF ILIAC (SPINAL) ABSCESSES.

(See page 648.)

DISCUSSION.

DR. WILLIAM J. TAYLOR: I wish to thank Dr. Young for bringing these cases for us to see. I have used this method of treatment several times in the last year with good results. There is one point to which I desire to call attention, and that is that instead of the curette I have used with advantage pieces of gauze on long forceps, and swabbed out the whole interior of the abscess. In that way you remove a large amount of granulation tissue containing tubercle bacilli. With this method I use thorough flushing with plain boiled water, the water being allowed to flow while the gauze-curette is being used.

With regard to the length of time that the drainage-tube is allowed to remain, my experience is that the sooner you get rid of the drainage-tube the better. With the method to which I have alluded I find that within a week, sometimes in a few days, I can remove entirely the drainage-tube, and although there is some discharge, the amount is small and the recovery is rapid, considering the extent of the disease.

DR. G. G. DAVIS: I think that the question of operation depends upon the peculiarities of the case. I should be inclined to leave the abscess alone where I thought it was not enlarging or that it would ultimately be absorbed. I think that it is hopeless to attempt to cure them by any direct action upon the diseased part. As Dr. Young has said, the attempts in the way of curetting have been failures, and any operative procedure that attempts to eradicate the bone disease will likely be a failure. If the abscess is small and does not show a tendency to increase, I believe that it would be better to let it alone. I remember two cases in which, after opening, the discharge continued profuse, and death occurred. I do not believe that the discharge is kept up by the condition of the abscess cavity, but by the tuberculous process in the bones themselves. While I should not hesitate to operate in a rapidly growing abscess in an individual more or less healthy, and where the promise of repair is moderately good, yet in such a case as I now have under observation, an adult, with probably some tubercular changes in the lung, who now has a fistula in ano, a tuberculous testis, and an iliac abscess on the right side, I have no doubt that if this abscess were opened the suppuration would be prolonged and the retrograde changes would be hastened. If, as I have said, the individual were moderately healthy and capable of reacting, I should do as Dr. Young has done.

DR. JOHN B. ROBERTS: I am interested in two points of the discussion. One is the expression of the opinion that a good many of these cold abscesses, or tubercular abscesses, should probably be allowed to go without opening because of the probability of absorption taking place. My own feeling has been that so few are absorbed that as soon as I see one I have been inclined to incise it, as the risk under antiseptic treatment is so slight. I should like to hear this point developed a little more.

The statement as to the rapidity with which these tubercular abscesses heal after opening, with only a small sinus and a moderate amount of discharge remaining, is interesting to me, because that has not been my experience, probably because I have not treated them so satisfactorily. I should like to hear this brought out more thoroughly.

The more radical operations of curetting and cutting down and trying to get rid of the carious bone, which have been vigorously advocated, does not seem to meet with the approval of the members who have spoken. That is a comfort to me, as it has been my practice to refuse such operations.

DR. M. PRICE: I have no experience in spinal surgery, but the observation of these two cases would lead me to send such cases to the man who would treat them in this way. Dr. Davis' criticism as to operation is in a measure outside of the scope of this discussion. It is a question whether or not you can benefit a man with tubercular deposits in various parts of his body. Pus is a foreign body, and it is doing damage no matter what part of the economy it is in, and should be removed. The fact that the patient is weak and broken down is no argument against operation. If there are any cases that would suggest waiting it would be the strong and vigorous, those who can combat disease and resist the poisonous effects of absorption of pus. My feeling is that we

should always remove pus, and drain if we can. I see no reason why the treatment laid down by Dr. Young is not the proper treatment in spinal diseases where the result will be fatal if the large majority of cases are left to nature. Even if a large proportion died it would be no argument against operation. I believe that the two cases shown are one of the best arguments in favor of this method of treatment. Both of the children show that they are in good condition. I am surprised that Dr. Davis should recommend the leaving of a large abscess, poisoning the patient under the possible chance of recovery. The pus is dangerous and should be removed. It is so in the pelvis, and the spine is no exception.

Dr. Davis: I am not aware that I said anything derogatory to Dr. Young's views or his method of treatment. It is simply a choice of cases. I believe that in Dr. Young's cases the choice was properly made. Against the adoption of incision in all cases of abscess I did speak. Dr. Price has asked the reason why we should leave pus. The pus of cold abscess is different from that of acute abscess. I cannot recall any case of acute abscess where I should hesitate to leave pus out, and when it comes to abscess in which the active organisms which were largely instrumental in the production of that abscess are dead, then you have simply a foreign body, a foreign body which is liquid to a great extent, and which at times does become absorbed, and one should consider well before opening it. In deciding whether or not to open these abscesses, I laid stress upon the condition of the patient. Dr. Roberts, with his usual modesty, suggests that some lack in his operative procedures may account for some of the results that he has had, but I am sure that all of us know the care with which he attends to his cases, and that this is a very insufficient explanation to account for their continued suppuration. The rest of us can take it for granted that if such results occur in the hands of a surgeon as careful as Dr. Roberts, they are as liable to occur in our hands. There are certain cases of abscess in connection with bone in which, if the abscess is opened, suppuration is thereafter continuous and more or less profuse, and in a markedly tuberculous patient will not infrequently lead to death.

I have no doubt at all that absorption of pus does take place, but, as Dr. Young pointed out, where the abscess is large and there is danger of rupture into adjacent cavities, or where there is a rapid increase in size, the indications for relief are clear. I should not expect absorption in such cases, nor should I hesitate to operate. Where the abscess shows no tendency to increase, particularly in a weak strumous individual, I should certainly adopt a conservative policy.

The President, Dr. De Forest Willard: I do not believe in allowing pus to remain in the body. As soon as we are certain that pus exists in any cavity we should adopt measures for its removal. In regard to the old theory that hectic fever resulted from these incisions—that was simply septic fever. A temperature sheet, such as has been shown, where after the operation the temperature on only one occasion reached 100°, shows that "hectic" fever is preventable. Moreover, in many cases where before operation the temperature has been from 103° to 104°, on the day following incision it will be found below 100°. This temperature of 104° burns the life out of these cases, and these are the ones that should be operated on to get rid of the poison. Tuberculous pus is dangerous if allowed to remain; it is a focus of disease, and from it new foci in other parts of the body may be developed. Therefore I believe in incision under thorough aseptic and antiseptic precautions, with thorough drainage and thorough curetting where it is possible. There is one caution to be observed when making through-and-through drainage—care should be exercised in the use of the curette on the peritoneal side of the abscess. The curette may cause little perforations, and then if, as is sometimes done, peroxide of hydrogen is injected, small quantities of pus may be forced through these openings.

These wounds can be kept aseptic. I know of cases that have been discharging for months, yet the wound has been kept absolutely aseptic, but if a fresh suppurative process is engrafted on these sinuses there will be a serious drain, and probably great danger to the patient. I am thoroughly satisfied at the operative treatment, not that it cures the original disease, but it relieves the drain on the patient, diminishes the fever, and, if accompanied by proper fixation and by hygienic measures,

permits the patient to become hearty and strong, in place of the wretched, worn, exhausted individual which we so often see as the result of poisoning from the absorption of tubercular pus.

Erosion of the vertebræ is a dangerous and also a difficult operation, and in the end the surgeon is never certain that he has eradicated the disease. That is the real objection to erosion. If we could be certain that we could remove all the disease, it would be worth all the time, trouble and risk which are required to reach the source of trouble. I do not believe that there is any operator so adept as to be able to work entirely around in front of the body of the dorsal vertebræ. I certainly have never succeeded except in cases where there has been a large deposit of tuberculous matter and where the body of the vertebræ has been broken down. In healthy dogs I have tried over and over after removing the head of a rib, but never succeeded without getting into the pleural cavity. In one case where there was a large tubercular mass in front of the vertebræ, pushing the pleura forward, I was able to pass a loop of tubing entirely around.

DR. YOUNG: The conservative method is a well-accepted form of treatment. There are on record two well-authenticated cases in which recovery followed where there were large abscesses in this region and the patients refused operation. They are those of Dr. Taylor, of New York, and the case recorded by Bradford and Lovett. Two years later the abscesses had disappeared. I have now under observation a case in which there was a large abscess which has now disappeared.

In speaking of rapid cures in these cases, I was speaking as a surgeon in chronic cases. By "rapid cure" a chronic surgeon would mean months. These cases discharge for six or eight months, perhaps a year longer. I am inclined to think that these cases represent a special group of cases—that they are iliac abscesses similar to psoas abscesses, and not to be distinguished from them except that very early we notice psoas irritation in these cases. The first symptom may be irritation of the psoas muscle, as demonstrated by the inability to extend the thigh beyond the normal line. Then, upon palpation, possibly a deep abscess may be discovered within a few days. Then the abscess will become larger, and this is the time for operation. In all these cases apparatus was applied early and continued. As soon as possible after operation a plaster jacket was applied, and afterward a plain brace or support of some kind.

EVIL RESULT OF OSTEOTOMY.

THE PRESIDENT, DR. DE FOREST WILLARD: I wish to show you a case which came under my notice a few days ago, and which illustrates one of the bad results that may follow osteotomy. I believe most enthusiastically in osteotomy for the correction of deformities, and in ninety-nine cases out of one hundred one can obtain capital results without pus. This case was operated on by another surgeon, and was done some years ago. You will observe that the limb is greatly atrophied and deformed. There is scarcely any muscular tissue left. The cicatrix is also exceedingly sensitive. I fear that ultimately amputation will be required. Although I am a strong advocate of the operation of osteotomy, I think it well to know the other side of the question. I presume that in this case septic infection with sloughing occurred. In the last three years I think that I have not seen a single drop of pus after an operation of this character. Every one has healed as a similar fracture of the leg.

DISCUSSION.

DR. WILLIAM J. TAYLOR: I have never seen such a result as has been shown following osteotomy, nor have I seen any pus. I have seen, however, in one case of simple fracture with no external wound, the patient die of pyæmia, the direct result of the fracture, and the post mortem showed extensive septic inflammation.

Dr. Willard discussed

ILIAC ABSCESSES, NON-SPINAL IN ORIGIN.

(See page 650.)

DISCUSSION.

DR. M. PRICE: Some time ago, while in Muncy, I fell in conversation with a man who in early life had hip disease. A few years ago a tumor appeared on the previously diseased side, and he came to Philadelphia and was examined by a dis-

tinguished surgeon, who told him that he had tuberculosis, and that the result would be fatal and nothing could be done. He consulted others, but no one would operate. He returned to his home and spent three or four months in bed. He insisted that the mass should be opened, but none of the local physicians would do it. Finally he took a razor and went in above Poupart's ligament, and at once a large quantity of pus escaped. In six or eight weeks he recovered and has since remained well. I have no doubt that that was an abscess of the character of which Dr. Willard speaks. We should never turn away any of these cases without a thorough investigation.

The other day a case came to the hospital. He was an epileptic, and fifteen weeks ago had fallen from a cherry-tree. A week later a tumor developed in the splenic region. On examination I thought that he had a splenic abscess. I made a small incision and two or three quarts of peritoneal fluid escaped. The peritoneum had evidently been injured, and a localized peritoneal dropsy had been the result.

I was recently asked by Dr. Keller to assist him in opening an abscess of the kidney. We carefully cut down on the abscess and evacuated two or three quarts of pus. The finger could be passed over the crest of the ilium toward the pelvis. The boy made a good recovery. This was evidently another case due to injury.

Dr. William J. Taylor: I have only one case bearing on this subject. An Italian, while lifting a heavy weight, felt something give way in the right side. In two weeks a tumor appeared midway between the anterior superior spine and the umbilicus. This gradually increased in size. I saw him in consultation, and came to the conclusion that it was some form of abscess. I made an incision and found a very extensive abscess extending around toward the right kidney, but outside of the peritoneum, evidently a perinephritic abscess. With drainage he recovered and the wound healed nicely, and he had no trouble for eighteen months. Then the whole thing recurred, and six weeks ago I again operated on an abscess in the same position. In three weeks it healed absolutely, and he is again well.

Dr. H. A. Slocum: I recall two cases presenting symptoms similar to those of iliac abscess. One was in an English-woman with a large scar in the iliac region, the result of an operation in England four or five years ago. I assisted in the second operation for inflammation in the right side, and found remains of the broad ligament in the scar on the left, showing that the abscess had been connected with the pelvis. In another case, which had been under observation for eight years and in which I advised operation, the symptoms presented before operation might have been mistaken for those of iliac abscess. The tubes, ovary and omentum formed a large mass which raised the abdominal wall three-fourths of an inch in the left iliac region. The whole mass was found agglutinated and was removed. She is now perfectly well, three years after operation.

Dr. James M. Brown: I can recall two cases from traumatism. The first case was that of a man who while supporting a heavy weight felt something give way in the left iliac region, incapacitating him for work for a few days. He afterward was compelled to give up work, and in a few months an abscess formed and opened above the crest of the ilium posteriorly. This man refused operation and died with albuminuria. In the second case the man fell, striking the left lumbar region. Here the same course of events followed, with the exception that the opening occurred anteriorly and the man recovered.

Dr. Willard: My object in calling attention to this group of cases was simply to emphasize the fact that abscesses in this fossa may occur independently of spinal, hip, tubal, or appendiceal disease. These cases show that abscess here is like other abscesses. I believe that pus in the body is harmful; if we can evacuate it safely we should do so, and as soon as it is probable that pus is present we should make an incision and explore. This prevents the abscess from extending and burrowing, and avoids the danger from high temperatures.

Dr. A. J. Downes exhibited a specimen of a

PULMONARY CALCULUS.

Mrs. R., aged eighty-nine, while eating breakfast on Saturday morning, September 29th, in her usual health, had a severe coughing spell. During the following

few days she had several similar spells. On Thursday, about 4 P.M., I was present during the worst and last one. While listening to the chest during this attack I found no air entering the left lung. The attack ended with a copious discharge of muco-purulent matter, slightly blood-tinged, which striking the basin gave a sound. It contained the calculus I present. Quite too large, it would seem to be cast up from the left bronchus, where it evidently had been. The patient has hardly coughed since, and has been entirely free from a bronchial irritation and expectoration she suffered from for about fifteen years.

DR. FRANCIS RUDEROW: I recall the case of a negro, forty-two years of age, admitted to the Episcopal Hospital with nephritis. He also had attacks of spasmodic asthma, and insisted that when the attacks came he felt a blocking in the region of the right bronchus. He suddenly died, and on autopsy we found a curious calcareous deposit in the left bronchus an inch and a quarter in length. This blocked the bronchus entirely and was undoubtedly the cause of death.

FOODS OF THE FUTURE.

"What will the man of the future eat?" The answer to this question has been undertaken, not by an imaginative writer, but by one of the greatest of living men of science, Professor Berthelot, of Paris; and it may be said at once that but for his scientific eminence and the undeniable facts upon which he bases his forecast, it would pass the limits of human belief. The epicure of the future is to dine upon artificial meat, artificial flour and artificial vegetables; drink artificial wines and liquors, and round off his repast with an artificial tobacco beside which the natural tobacco of the present will seem very poor.

Wheat-fields and corn-fields are to disappear from the face of the earth, because flour and meal will no longer be grown, but made. Herds of cattle, flocks of sheep and droves of swine will cease to be bred, because beef and mutton and pork will be manufactured direct from their elements. Fruit and flowers will doubtless continue to be grown as cheap decorative luxuries, but no longer as necessities of food or ornament. There will be in the great air trains of the future no grain or cattle or coal cars, because the fundamental food elements will exist everywhere and require no transportation. Coal will no longer be dug, except perhaps with the object of transforming it into bread or meat. The engines of the great food factories will be driven, not by artificial combustion, but by the underlying heat of the globe. In order to clearly conceive these impending changes, it must be remembered that milk, eggs, flour, meat, and, in fact, all edibles, consist almost entirely (the percentage of other elements is very small) of carbon, hydrogen, oxygen and nitrogen. Oxygen and hydrogen are the two gases which, when combined, form water. Oxygen and nitrogen mixed are the air we breathe. Carbon forms the charcoal of wood, is the main constituent of coal, and as carbonic-acid gas in the air is the chief food of the vegetable world, these four elements, universally existing, are destined to furnish all the food now grown by nature, through the rapid and steady advance of synthetic chemistry.

Synthetic chemistry is the special science which takes the elements of a given compound and induces them to combine and form that compound. It is the reverse of analytic chemistry, which takes a given compound and dissociates and isolates its elements. Analytic chemistry would separate water into oxygen and hydrogen, and synthetic chemistry would take oxygen and hydrogen, mix them, put a match to the mixture and thus form water. For many years past synthetic chemistry has had an eager eye upon food-making. It has already progressed so far that several great agricultural industries have been destroyed by its advancement, compounds which were once obtained by plant growth in the fields being now entirely furnished by chemical laboratories and direct manufacture.—*Public Opinion.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Cold Water as an Antipyretic.

Dr. Fisher has arrived at the following conclusions:

1. That cold water is the best antipyretic used to-day.
2. That it is easily obtainable, and is therefore adapted to all classes of cases, both rich and poor.
3. The mode of application is so simple that it adapts itself to the hospital, and equally as well to private practice, and can be applied without any distinct training.
4. Cautiously given it stimulates.
5. Carelessly used and longer than required, it depresses, and will produce subnormal temperature.
6. That rectal temperature should be taken, and the bath at once discontinued when temperature falls to 101°, as it will then continue to fall.
7. That a stimulant administered before the bath may be necessary, and should be given where there is a feeble heart.
8. That the temperature indicates when to commence, and when, also, to discontinue the hydropathic treatment.
9. Unnecessary blanketing after the bath is injurious, and will produce copious perspiration, which I believe weakens the patient.
10. The temperature of the room should always be between 68° and 72°.—*Post-Graduate.*

Poisoning by Guaiacol.

Prof. Oscar Wyss (*Deutsche Medicinische Wochenschrift*) cites the first fatal case of guaiacol poisoning and directs attention to the toxic symptoms as follows:

A girl nine years of age, who had been accidentally given 5 c.c. (75 drops) of guaiacol. In a short time she became unconscious; the conjunctivæ became injected, the corneal reflexes diminished and the pupils no longer reacted to light; there were frequent attempts at vomiting and the saliva flowed from the mouth in large quantities. The pulse became rapid, the sensibility of the skin much diminished. Finally the patient began to vomit; the physician detected the odor of guaiacol. The stomach was washed out, but she did not rally. The cyanosis gradually diminished, and instead of it a deadly pallor was observed; the respiration became frequent. Three and a half hours after the guaiacol had been swallowed the patient passed 100 c.c. of brownish-red urine.

The spleen and liver soon enlarged, and the temperature fell to 35.5° C. (96° F.) and small hemorrhages were observed upon the skin of the arms and legs. The urine contained albumen, blood and casts, and Ehrlich's carbolic acid test was positive.

Jaundice soon appeared, the stupor increased and the patient died on the third day.

The autopsy revealed an acute gastritis and enteritis, parenchymatous degeneration of the liver, acute hemorrhagic nephritis, parenchymatous degeneration of the heart muscle, and ecchymoses in the pleura, peritoneum, endocardium and pericardium. The spleen was much enlarged. Kobert in his text-book on "Intoxicationen" points out that after 1 gram (15 drops) doses of guaiacol slight appearances of poisoning may supervene. These are characterized by a burning feeling in the stomach, nausea, etc. In one case in which 15 grams (3¾ drachms) were accidentally taken by a patient in the Dorpat Clinic, the stomach was immediately washed out and the patient was rescued. However, unconsciousness set in, the pupils became contracted, the breathing irregular and the intensely dark appearance of the urine was very noticeable.—*Canada Lancet.*

Advice as to Stimulants.

In a very interesting work by Dr. George Herschell, of London, called "Health Troubles of City Life," the writer says: "Stimulants never increase the natural capacity of the brain. They can only abstract for the purpose of work in hand some of the energies which are sorely needed to repair and restore a brain which has already been taxed to the furthest limit which is consistent with health. To remove the sense of fatigue caused by overwork by the consumption of alcohol is to close one's ears to the voice of nature. The weariness of the brain is a protest against further exertion until recuperation has been obtained by rest; and if the weary feeling is deadened or destroyed by adventitious means, nature will exact her penalty. When the overworked man of business, having been on his legs all day and feeling fit to drop, with a sensation of 'all-goneness' about the region of the stomach, rouses himself with whatever he is in the habit of taking, be it whisky, champagne, or even tea or coffee, he does not add one atom of force to his stock of energy, although he fancies he does, but having put to sleep his sense of weariness, simply appropriates some of his reserve for the present necessity. He has accepted a bill at a short date to which a ruinous rate of interest is attached, and his resources will not allow him to make many repetitions of the experiment. His account at the bank of life will soon be overdrawn. Alcohol cannot add one iota to his reserve of nervous energy, but it may delude him into exhausting it. The busy man should once for all rid himself of this fancy that he can create by artificial means an abnormal store of brain-power. He cannot enlarge the limits which nature has set up."—*Canada Lancet.*

Vomiting of Pregnancy.

Lutaud (*Rev. Obstet. et Gyn.*) states that vomiting of pregnancy is best treated by cocaine. The action of this drug is often strengthened by combining it with antipyrin. Thus the following prescription:

Chlorhyd. cocaine.....	gr. iss
Antipyrin.....	gr. xvj
Aq. dest.....	ʒ iv

Sig.: Teaspoonful every half-hour until the vomiting ceases.

If the stomach will not tolerate this quantity of liquid, 10 drops of a one and a half or two per cent. solution of cocaine are administered, repeated at one or two hour intervals.

At times the application of cocaine to the os is extremely valuable. The following prescription may be used:

Hydrochlor cocaine.....	gr. xvj
Ext. bellad.....	gr. iv
Vaseline.....	ʒ ss

Cotin's method of dilating the os with the finger sometimes causes immediate cessation of vomiting. Occasional success will follow Routh's procedure, which consists in exposing the uterine neck by means of a speculum and painting with tincture of iodine. In cases of moderate severity the following mixture will be found serviceable:

Tinct. iodine.....	ää ʒ ij
Chloroform.....	

Sig.: Five drops night and morning at meal-times, taken in seltzer-water.

—*Thera. Gazette.*

Bradycardia of Convalescence.

Dehio, quoted in *Deutsche Med.-Zeit.*: Slowing of the heart's action may be produced either by a lesion of the motor structures in the organ itself, or by irritation of the inhibitory fibers of the vagus, or relative paresis of the augmentor fibers of the sympathetic. We possess in atropin, which paralyzes the nerve-endings of the vagus in the heart, a means by which we can determine whether the slowing is cardiac or extracardiac. If, after the injection of atropin, the pulse beat is considerably accelerated, the fundamental condition is extracardiac.

The slow heart of convalescence is generally associated with a subnormal temperature, and does not continue, as a rule, beyond a few days or a week. It is sometimes interrupted for a time by a normal or even hypernormal pulse rate, the interruption being either transient or lasting for hours or even for days. The pulse is generally small and easily compressible, often dicrotic and sometimes irregular. Disturbances in the general condition and organic changes in the heart are wanting in the slighter cases. In other cases there may be observed all the symptoms of an acute though not necessarily very severe cardiac debility—irregular action of the heart, increase of the cardiac dullness, with systolic murmurs over the left heart. In such cases the bradycardia is not an independent functional anomaly, but only one of the phenomena of the debilitated state of the heart. Atropin accelerates the pulse to a much smaller degree in bradycardia of convalescence than it does in good health. This refractoriness of the heart toward atropin is proof that the condition under consideration is not due to irritation of the vagus, but to something in the heart itself; and it is to be taken as an expression of debility of the organ. This is not due to demonstrable changes, such as myocarditis, which have been described as occurring after infectious diseases, but rather to the action of ptomaines upon the heart.—*Glasgow Medical Journal.*

Virulence of Poison Ivy.

Poison ivy and the characteristic inflammation produced by it are known in different localities by several aliases. It appears not only as a vine but as a bush of considerable size, and grows abundantly almost everywhere.

The virulent principle of this plant, says an eminent specialist on diseases of the skin, is a volatile acid which exists in all its parts, especially in the leaves. All persons are not affected by it; some handle it with impunity. Actual contact with the plant is not always necessary for the production of the poisonous effects on account of the volatility of its active principle, and there is good reason to believe that persons sensitive to the poison not infrequently suffer from passing by places where the vine grows abundantly.

The plant is supposed to be most actively virulent during the flowering season, in early summer, but cases occur with great frequency during autumn. Even in winter twigs and stems are alive to mischief to those who handle them.

One writer tells of a patient who cannot drive through the woods where the poison sumach grows without subsequently suffering with the characteristic inflammation, and that in merely passing to the leeward of a field where the farmers were burning brush has been sufficient to evoke the eruption. The poisonous influence of the plant is transmitted with the greatest facility on clothing and other articles in use.—*West. Med. Rep.*

Treatment of Vaginitis.

Lutaud (*Revue Obstetricale et Gynecologique*): The treatment of vaginitis differs little, whether it be simple or specific. The physician should, above all, consider the *acute* and *chronic* vaginitis in the therapeutical point of view.

(*a*) *Acute Stage.* — Here the speculum should not be employed. The patient should be kept as quiet as possible, and walking, coitus, and all physical exercise forbidden. Frequently repeated injections (every six hours) with Esmarch's douche with two liters of a one per cent. solution of boric acid. Emollient injections, such as starch, flax-seed meal, or decoction of poppy heads, may also be employed. If paln is severe, one of the following suppositories is given every evening:

Ext. opii.....	centigm. j
Ol. theobrom.....	gms. iv

M. Ft. supposit. no. 1.

This may be replaced by a little injection

containing 15 drops of laudanum. For bladder symptons (tenesmus, pain during micturition), poultices, with laudanum sprinkled over them, bromide of potassium, emollient drinks, and alkaline diuretics are to be prescribed. It is well in these cases to discontinue wine, but light tea may be taken.

(*b*) *Chronic Stage.*—An injection three times a day is to be given with one of the following:

Acid carbol....	gms. v
Alcoholis.....	gms. x
Ess. thym.....	gtts. xx

M. For two quarts of water.

Hydrarg. bichlor	centigms. xxv
Acid. tartaric	gm. j

M. For two quarts of water.

Potas. permanganat.....	gms. x
Aq. dest.....	gms. cc

M. A tablespoonful for two quarts of water.

This last is the best remedy for gonorrhœal vaginitis; if it did not soil linen, it would be perfect. In rebellious cases, or when it is necessary to act rapidly, a Sims speculum is introduced and the vagina is painted with a solution of nitrate of silver (2 grammes in 30 grammes of water).

Before withdrawing the speculum, a large tampon imbibed with the following is introduced:

Acid. tannic.....	gms. ij
Cocain. hydrochlorat.....	centigms. x
Glycerini.....	gms. cxx

The tampon should be left in place for two days. No matter what may be the treatment applied in chronic vaginitis, the cure may always be hastened by the vaginal dressings, which isolate the parts and absorb the secretions. Simple dry cotton tampons are good, but when made with iodoform or salol gauze are preferable.—*Annals of Gynæcology.*

Acute Anterior Poliomyelitis.

Von Kahlden (*Centralbl. f allg. Pathologie*) reviews recent writings on the morbid anatomy of this disease, with special reference to its parenchymatous or interstitial origin. In three of Rissler's cases death occurred from six to eight days after the onset. Here there was advanced degeneration of ganglion cells, but very little change in the interstitial tissue. Rissler concludes that Charcot's view that the primary lesion is in the ganglion cells is the correct one. Two other cases in which death occurred after seven weeks and eight years respectively are reported by the same writer. From his own three cases, all of some years' standing, the author also adopts Charcot's view, as neither the destruction of ganglion cells in groups nor yet the relatively very slight disappearance of nerve fibers was to be explained by a primary interstitial lesion. In two cases of old amputation the author also saw this atrophy of ganglion cells in groups. He records an investigation into two further cases of what he terms "atypical poliomyelitis." Goldscheider concludes from his case that some irritant having established itself in the vessel wall led to marked vascular dilatation and endothelial overgrowth, which spread to the neuroglia. The author points out that Goldscheider here uses the term "inflammation" in quite a new sense. Dauber, from an examination of a case of five days' standing, maintains the interstitial origin of the disease. The author would class this case, as well as Redlich's, as atypical. Siemerling maintains that in his two cases of ten days' and eight months' standing the disease was an acute myelitis, the anterior horns being chiefly involved. The interstitial change along with the vascular lesions showed, according to this writer, that the supporting tissue was the chief seat of the disease. The author thinks that the value of quite recent cases has been overestimated in settling this question. It is, then, often open to doubt whether the disease is really poliomyelitis, or they may be atypical cases. Slighter cases should be used to determine the starting-point of the disease. The author attaches overwhelming importance to the disappearance of ganglion cells in groups. He maintains that any lesion affecting these cells secondarily through their blood supply must be diffuse. There is no evidence why a non-corpuscular irritant circulating in the blood should involve not only the spinal cord alone, but so small a part of it as the anterior horns. The rapid onset of the disease is not explained by a secondary affection of the ganglion cells. The author refers to the intact condition of many nerve fibrils in this relation. He maintains that in his own and other reported cases the changes in the interstitial tissue do not need the assumption of an interstitial origin for anterior poliomyelitis.

Treatment of Mumps.

Dr. A. Martin (*Sem. Med.*): During a recent epidemic of mumps among soldiers, the author successfully resorted to the following treatment:

From the outset, he instituted buccal antisepsis, which, when rigorously done, according to his observations, diminishes the chances of testicular complication. He therefore had his patients gargle and cleanse the mouth as often as possible with solutions of thymol, carbolic acid or very hot 4 per cent. boric-acid solution.

Besides, during the first days of the disease he administered antipyrine in daily doses of 2–3 grammes (30–45 grs.). This, he states, more rapidly effects the resolution of the inflammatory process than do sodium salicylate and other remedies; moreover, it acts more promptly on the fever and pain.

In orchitis caused by mumps, pilocarpine subcutaneously in doses of 1 centigramme (1–6 grs.), repeated once daily, is said to have promptly diminished the pain from the first evening on, and to have lowered the temperature, which became normal on the third day. The swelling of the testicle disappeared between the eighth and tenth days. After the acute period of orchitis was passed, the patient was submitted to a tonic treatment (cod-liver oil, nux vomica, cinchona extract, meat powder, sulphur baths, etc.) for the purpose of preventing testicular atrophy.

What Cases Shall We Send to Colorado?

Dr. J. N. Hall (Texas *Sanitarium*): As this is quite a fair though slightly biased statement of the indications pointing to the high altitude of Colorado, it is deemed worthy of an extensive recapitulation.

1. *Phthisis.*—(*a*) The great benefit is obtained only when sent in the incipient stage. (*b*) Those cases in which digestion is fair do the best. (*c*) Little advantage to fibroid phthisis.

2. *Acute Pneumonia.*—Do badly if sent before resolution has occurred.

3. *Emphysema.*—Is generally contraindicative of heights in general, and Colorado is no exception.

4 *Chronic Bronchitis.*—Especially when bronchorrhœa is present does splendidly.

5. *Dyspnœa.*—Generally speaking, this symptom is really intensified by high altitudes anywhere.

6. *Pleurisy.*—Cases requiring tapping so commonly show tubercular trouble that they had better be sent as early as possible after the tapping, as prophylactic measure.

7. *Asthmatics.*—Advantages to these patients as a class very questionable.

8. *Disease of Circulatory Apparatus.*—High altitudes is a menace to all such subjects.

9. *Chronic Malaria.*—These cases do well, as they will in any non-malarial climate.

10. *Gynæcological and Nervous Cases.*—No advantage to these.—*Am. Pract. and News.*

A New Treatment of Tapeworm.

Dr. Dronke, in the treatment of tapeworm, associates the three most powerful tenifuges, thus hoping to obtain a more active therapeutic influence. His formula is:

Honey	ʒ v
Ethereal ext. pomegranate..	ää gr. vijss
Eth. ext. male fern	
Kousso flowers	ʒ v

M. Sig.: Divide this into three parts and take them in the morning with intervals of ten to fifteen minutes, the day before the patient living, of course, on a reduced diet.

One or two hours after taking the preparation administer an ounce of castor oil. Have the patient pass his stools into a vessel filled to the brim with warm water to avoid breaking the worm.—*Lancet Clinic.*

Electricity in Amenorrhœa.

Panecki (*Therap. Monatsch.*) has found electricity, and particularly the faradic current, the most successful means of dealing with amenorrhœa. It is necessary that the poles should be introduced into the uterus and be allowed to act there. This treatment is well borne, and the current can be increased at each sitting, the number of the latter required averaging from five to thirty, and their duration five to fifteen minutes during successive days. The author's experience includes 18 cases in which the cure of the condition was established a year or more ago, the patients still remaining well. One of these, a married woman aged 31, had never menstruated, though she was subject to periodical affections (severe headache, etc.). The treatment on various lines had extended over six years, but with absolutely no success. The author, at the expiration of one of these periods, commenced the application of the faradic current, and after twenty-eight successive sittings a small flow became apparent. During the following interval six more applications were made, and the patient is now well and relieved of all symptoms.—*British Med. Jour.*

Salicylic Acid in Acute Rheumatism.

Dr. Bourget (*Rev. de Ciencis Med. de Barcelona*) concludes as follows: Absorption of salicylic acid by the skin is very rapid and intense. The skin of youthful individuals is most absorbent, while persons with white skins are more so than those with brown or black. The rapidity and intensity of its action are dependent upon the vehicle in which the acid is dissolved. and of these agnine is the best. Fatty substances greatly facilitate its penetration through the skin, while with glycerine or vaseline it is less. Treatment of acute articular rheumatism with a salve of salicylic acid and agnine is recommended. It is less serviceable in other forms of rheumatism, though it might be of value as an adjunct in massage. In general rheumatism it is inactive.

A Case of Angina from Copaiba Balsam.

A young man, 22 years of age, took copaiba and eubeb opiate for some days for blennorrhagic urethritis. On the seventh day appeared a confluent exanthematous rash, simultaneously with redness and congestion of the pharynx, palate and tonsils. The uvulva was enlarged from œdema. Over the whole surface of the mucous membrane of the throat appeared a miliary eruption. The third day after the appearance the eruption disappeared. The patient had constant mouth-breathing and consequently chronic pharyngitis, due to post-nasal obstruction from adenoid vegetations.—*Bulletin Med.*

Vomiting of Pregnancy.

Dr. Berry, in the *Memphis Med. Monthly*, says that where the patient is of a nervous temperament, cannot retain even a sip of tea or water, a formula composed of 1 ounce of fluid extract of valerian, 16 minims of Fowler's solution of arsenic, and 1 drachm of sodii bicarb. has never failed in his hands of producing prompt relief, when given in teaspoonful doses every two or three hours.

To Hide the Taste of Chloral.

Dr. E. Holland calls attention to the fact that the taste of chloral hydrate is effectively masked by lemonade. Two or three drachms of the syrup should be placed in a tumbler with about 2 ounces of water. If to this is added about 2 ounces or so of gaseous (bottled) lemonade, the mixture may be drunk at leisure, and the soporific action of the drug is in no way impaired.—*Med. Bulletin.*

PATHOLOGY.

The Diphtheria Bacillus.

Abel (*Deut. med. Woch.*) refers to the fact that diphtheria bacilli may be found in the throat and nasal secretion after the end of the disease, and when the patient is apparently well. The period during which such patients can convey the disease lasts only a short time, corresponding apparently at most to five weeks. The author, however, reports a case in which these bacilli were found sixty-five days after the disappearance of the membrane from the throat. There was at this time a fibrinous exudation in the nose from which they could be cultivated and experimented with. It has been shown that the nasal mucous membrane is a good cultivation soil for the diphtheria bacillus. This case was an example of a fibrinous rhinitis upon a diphtherial basis. Nasal diphtheria is a rare disease, with fœtid nasal discharge and severe symptoms. Fibrinous rhinitis is also an acute process, but the pharynx escapes and the temperature and general condition remain undisturbed. It appears in most cases to be a mild form of diphtheria, but it is not always so, for other micro-organisms may excite it. Patients suffering from it are not suspected and may thus convey the disease to others. The author thinks that diphtheria patients should not be discharged until a bacteriological examination has proved the absence of diphtheria bacilli. Experiments show that the bacilli cultivated from fibrinous rhinitis are virulent. The author records such a case in a boy, aged 9 years, in which colonies of virulent diphtheria bacilli were found along with the strepto and staphylococcus The boy had not suffered from diphtheria, but his mother had just recovered from it. The bacilli disappeared when the membrane did. The author refers to another similar case, also proved to be due to the diphtheria bacillus.

Contagiousness of Cancer.

At the eighth meeting of the French Congress of Surgery, held at Lyons, October 9th to 13th (*Sem. Med.*, 10th), Guelliot, of Reims, presented a communication embodying the results of an inquiry as to the contagiousness of cancer begun in 1891. The number of cases collected by him in which cancer appeared to have been communicated by contagion was forty. In the author's opinion his facts show: 1. That cancerous affections are unequally distributed in adjoining districts, and that neither heredity nor consanguinity is adequate to account for this. 2. That there are real cancer houses, the dwellers in which, though having no link of blood relationship between them, are successively or simultaneously attacked by malignant tumors. 3. That cases of cancer atttacking two persons living together are relatively frequent. Of 100 such cases, published and unpublished, in 85 the persons attacked were man and wife; in 8 they were medical practitioners who had been specially engaged in the treatment of cases of malignant disease. According to the author these facts tend to show that cancer is transmitted, directly or indirectly, and that it runs its course as an infectious disease with the average incubation of from a few months to two years, a primary lesion, then generalization. In discussing the paper, Delore, of Lyons, stated that cancer seemed to him capable of being transmitted by pregnancy. Fifteen years ago, at the congress of Blois, he had brought forward a case in point.

THERAPEUTICS.

Lactophenin.

Roth (*Wien. klin. Woch.*) discusses the use of this drug in acute rheumatism. It has hitherto been chiefly used as an antipyretic, hypnotic and antineuralgic. The author draws attention to the occasional failure of the salicylates in acute rheumatism, and to the dangers at times attending the use of antipyrin, antifebrin and even sulphonal. He has noticed after lactophenin a temporary feeling of weight and heat in the epigastrium, which has disappeared on further use. Occasionally there has been some cyanosis, but without other symptoms. The dose given has been from 5 gr. to 1 gr., and this may be increased up to 6 gr. in the day. He refers to the use of this drug in enteric fever by v. Jaksch. Lactophenin has also been used in pneumonia, influenza, erysipelas, acute febrile tuberculous affections, scarlatina, sepsis, and acute and chronic rheumatism, but the number of cases of acute rheumatism is small. The author gives details of 8 cases of this disease, and refers to 20 more in which he has used lactophenin with good results. He concludes (1) that the pain and swelling disappear generally within forty-eight hours; (2) that the temperature continues low; and (3) that no unpleasant by-effects were observed, notwithstanding large doses. He has also found lactophenin useful in some cases of chorea and in the pains of locomotor ataxy. Lactophenin is worthy of being placed along with the salicylates as an antirheumatic.

Menthol in Diphtheria.

F. Kastorsky (*Vratch*, No. 24, 1894) reports 37 cases of diphtheria (in 3 adults and 34 children) treated and cured by painting with a 10 per cent. alcoholic solution of menthol. The paintings, by means of a piece of cotton wool, were usually carried out three times daily. In some cases, however, a single free application was followed by complete disappearance of false membranes within two days. A marked improvement in the patient's general condition was invariably noticed from the beginning of the treatment. The same simple method was successfully practiced by the author in numerous cases of anginas of various forms, and by Trutovsky in a group of cases of scarlatinal diphtheria. The paintings are said to be painless and quite harmless.

Duboisin as a Hypnotic

P. S. Skuridin (*Vratch*, 1894, No. 21) used hypodermic injections of duboisin in 21 cases of sleeplessness in the insane, the dose varying from $\frac{1}{150}$ to $\frac{1}{75}$ grain, and the grand total of injections amounting to 360. In 153 (42 per cent.) cases the duration of induced sleep exceeded six hours, while in 126 (35 per cent.) it oscillated between four and six hours, and in 62 (18 per cent.) was under four hours. In 19 (5 per cent.) the drug failed altogether. The writer comes to the following conclusions: (1) Duboisin will occupy a prominent place among hypnotics for the insane; (2) the best results may be expected in epilepsy, periodical insanity, and acute mania and mental confusion; (3) the hypnotic effect is a secondary phenomenon, developing consecutively to the subsidence of a motor or muscular excitement. Hence the drug proves most useful in insomnia caused by intense motor excitation. In sleeplessness depending upon illusions, hallucinations or organic brain disease, but unaccompanied by distinct motor disturbances, the remedy remains inefficacious; (4) the drug is free from accessory ill effects.

Treatment of Seborrhœic Eczema in Children.

Feulard (*Jour. des Prat.*) observes that attention must be given in the first place to the diet, which should be limited to milk, with the addition, in older children, of eggs. In the local treatment the first step is the removal of crusts, which may be effected by using warm coal-tar lotions, preceded, if necessary, by poultices. After the crusts have been removed he uses gauze compresses soaked in a solution of resorcin (6 in 1,000). These are kept constantly applied to the scalp by day, and are applied frequently to the face. By night an ointment is used, consisting of one part of balsam of Peru to 30 parts of vaseline. Later he uses fine starch powder or a powder consisting of equal parts of starch and carbonate of bismuth. Recovery is rapid if the instructions as to diet are strictly observed and the dressings used with regularity.

GYNECOLOGY.

Treatment of Distention of the Fallopian Tubes.

At the late meeting of the American Association of Obstetricians and Gynæcologists Frank. A. Glasgow, of St. Louis, read a paper which was intended to bring berore the profession a method of curing tubal distention by means of intrauterine treatment in contradistinction to cœliotomy and removal. By this means the uterine ends of the tubes are made more patulous, and a discharge takes place from the tube through the uterus. The author called attention to the fact that the tubes, so far as his observation goes, are always pervious at the outer extremity of the cornu; hence, when removing them, we must always clamp them before cutting. The obstruction must be within the uterine wall, probably in the endometrium; hence gonorrhœal inflammation is not an adhesive inflammation, and therefore it does not follow that the tubes have a true atresia following this inflammation. His opinion was that the closure is due to a swelling of the endometrium, and hence a closure at the uterine end takes place. When this inflammation and swelling are overcome by pressure and antisepsis the tubes become patulous again. The intra-abdominal pressure will cause fluid in any pendent portion of the tube to ascend into the uterus. The foregoing procedure can be carried out in three different ways: 1. By gradually packing with gauze without anæsthesia. 2. By rapid dilatation of the cervix and packing with gauze after curetting. This is done under anæsthesia. 3. The author's own method of dilating by means of antiseptic or sterilized elm-bark tents. These tents are small strips of elm bark, made just long enough to enter the cervix completely and not press on the fundus. They should be kept in an alcoholic solution of mercuric chloride (1 to 4,000) and have a short string attached, by means of which they may be withdrawn. They are partially broken in a number of places for the purpose of making them more pliable. They may be dipped into glycerine or water just before introduction. These tents may be used when it would be impossible to pack with gauze. He had treated twenty or more cases during the past year, and did not recall one in which he did not get some discharge from the tent. All the cases were either cured or very much benefited.

Cancer of the Pregnant Uterus.

Hernandez (*Archives d'Obstet. et de Gynec.*) concludes, from personal experience and statistics, that the following rules should guide: 1. In any case where cancer is detected in pregnancy the uterus and appendages should be removed at once if possible, whatever be the stage of gestation. 2. The surgeon should be careful to prevent all contamination of the operation wound by cancerous products and to remove the whole new growth. 3. Having isolated the new growth by a few sutures, he should, in a case in the first three months of pregnancy, perform vaginal hysterectomy; after the fourth month Mackenrodt's abdominal hysterectomy will be called for. Before the middle of the seventh month the uterus is to be removed at once, although the child may be alive. If the child be viable, Cæsarean section must first be performed, the uterus being removed afterward. 4. When the cancer is too advanced to allow of its removal, the surest way to save the child must be considered. 5. Early diagnosis can alone insure anything like a definite cure, hence it is our duty to look out for uterine cancer in pregnant women. In conclusion, in order that we may learn how far a permanent cure is possible, all cases should be accurately recorded. The state of the operation cicatrix should be reported when death occurs after recovery from the operation.

SURGERY.

Appendicitis.

W. G. McDonald, of Albany, presented to the American Association of Obstetricians and Gynæcologists a paper embodying the results of a clinical study of 84 cases. He thinks that out of the great mass of literature on the subject three important landmarks are established: 1. That for all practical purposes all inflammatory processes in the right iliac fossa arise from the appendix. 2. That practically the appendix is always intraperitoneal, and that any operation undertaken for appendicitis that does not involve the entering of the peritoneum is false in its surgical conception. 3. That idiopathic peritonitis does not occur. That many cases diagnosticated as such are really cases of perforating appendicitis. The author classified the varieties: 1. Acute perforating, fulminating appendicitis with general peritonitis. 2. Acute suppurating appendicitis with local plastic peritonitis and abscess. 3. Subacute appendicitis, variously termed catarrhal, chronic, relapsing or obliterating appendicitis, or appendicular colic. The perforation occurs very much earlier than is commonly believed. Acute suppurative appendicitis with local peritonitis presents the most favorable field for operation during the attack. The removal of the appendix is to be undertaken with great circumspection when it lies in the walls of an abscess cavity. The third group of cases does not require operation during the first attack, but if repeated attacks occur, operation during quiescence is demanded. Operative results in these cases are most favorable.

Cancer of the Kidney.

Alm (*Hygiea*) publishes the following case: A man, aged 39, had for six or seven years been subject to recurrent attacks of hæmaturia, at first only a few times yearly, but during the last three years oftener. The attacks came on independently of exertion or any other cause, and were not, as a rule, preceded or followed by any pain. Between the attacks the urine had been normal, but it had during the last years shown a trace of albumen. Only once, a few years ago, had he passed a small stone, the size of a pin's head. No tenesmus, not even during the attacks. Three years ago a hardening began to be felt under the right costal margin, and this has gradually increased in size until a year ago, since which time the patient thinks it has increased more rapidly. The tumor has never been tender, but on examination there has been slight pain. As the attacks of hæmaturia have become more frequent, the patient's general health has been reduced. The tumor, which could be felt midway between the costal margin and Poupart's ligament, was hard and almost round, the size of a man's fist. It was freely movable and could be pushed up so that its upper part disappeared under the costal margin. Its surface was somewhat uneven. The ascending colon ran obliquely across it. Nephrectomy was performed, as the left kidney was found normal and no metastases were detected in the peritoneal cavity. The patient made an uninterrupted recovery. On examination the tumor was found to be a primary carcinoma. That the hæmaturia from the first, six or seven years ago, was caused by the malignant new growth the author believes for the following reasons: There had never been any symptoms of stone or disease of the bladder. All the symptoms pointed to the kidney being the cause of the bleeding. Only once a very small stone had passed, but too small and smooth to cause hæmaturia; in the extirpated kidney there was no concretion found, and in the left none could be felt. Although cases of hæmaturia occur when on laparotomy nothing pathological can be detected, when as in this case a malignant tumor appears after a few years' time, is it rash (the author asks) to conclude that this has been the cause of the hæmaturia from the first?

Congenital Dislocation of Hip.

Bradford (*Ann. of Surg.*), from a general review of the literature of the subject and from his own experience, comes to the following conclusions: (1) That the methods of treatment by traction, or by mechanical means, crutches, splints, recumbent traction, with or without tenotomy, do not effect a cure; (2) correction by means of forcible reduction without incision can be applicable in but few cases and is not reliable; (3) that the method of operative reduction offers the best prospect of a cure. The method at present, however, involves risks and is not certain in its results, but it is to be expected that further experience will give greater precision and more certain results, as no inherent difficulties lie in the way of operation; that the condition of the shortening of the muscles, the shortened condition of the anterior bands of the capsular ligament, forms an important obstacle to complete reduction, and that these fibers should be thoroughly divided, and this is best done, according to the author, from in front rather than from behind. Myers (*ibid.*) discusses the same subject. Of 113 cases of which he has notes, in none of them was there pronounced flexion or adduction; 31 per cent. suffered from pain at times, especially during periods of very rapid growth. The attacks of pain were generally recurrent, and these cases seemed to show a considerable amount of shortening. The author thinks it improbable that the true reposition can be made without an open operation, since the originally shallow acetabulum is generally still further filled up, and the hour-glass form of the capsule would itself prevent replacement. By conservative treatment a great deal can be accomplished for these cases in some instances. In view of the good results already obtained by operation, and the even more promising character of the latest reports, we may, the author thinks, undertake the treatment of these cases with the assurance that we can benefit them very materially in a comparatively short time.

Strophanthus in the Treatment of Dipsomania.

Dr. Skworzow accidentally discovered the value of this drug in a case of an old toper of sixty-three, who, during dipsomaniac attacks, was accustomed to drink large quantities of brandy. Strophanthus was given on account of weak heart's action and an intermittent pulse, in doses of 7 drops three times a day. After the first dose the patient was seized with nausea, and had such a repugnance to alcohol that he stopped its use then for good. In two other cases he also succeeded by the use of this drug in aborting the attack at once. In all these three cases it produced nausea and profuse sweating, which symptoms are rarely observed in abstemious persons. It is worthy of note that in none of these cases was the sudden withdrawal of alcohol followed by delirium, as is usually the case.—*Lancet Clinic.*

Painful Peritoneal Adhesions.

Nicaise (*Rev. de Chir.*) states that the use of antiseptic methods and the consequent development of antiseptic surgery have made surgeons better acquainted with peritoneal adhesions, and have led to their successful treatment by operation. These adhesions may give trouble by disturbing the functions of implicated organs, and by exciting pain. The painful sensations vary in character and intensity in different cases. They may be caused by displacement of the organs to which the adhesive bands are attached, or by constriction of the intestinal canal. The pains in the latter condition are often very severe, and of a similar nature to those of hepatic and renal colic. The diagnosis of peritoneal adhesions is often very difficult; in some cases their existence can be assumed only by a process of exclusion, while in others certainty as to their presence or absence cannot be attained except by an exploratory laparotomy. The author is of opinion, however, that a diagnosis may be made in many cases by close inquiry concerning such details as the previous occurrence of abdominal inflammation; the seat of the pain, and the relation of such seat to that of old inflammatory attacks; the time when the pain comes on with regard to the taking of food; and, in females, to the periods of menstruation. As many peritoneal adhesions become longer and thinner, and have a tendency to disappear, there should be no hurry in having recourse to operative treatment. When, however, they cause very severe and frequently renewed pain, although the compression of an abdominal belt or bandage or massage may give relief, the only method of dealing effectually with such trouble is the performance of laparotomy and the destruction of the adhesions. The cure that may be thus effected will be complete and permanent; but, it is pointed out, as laparotomy is a serious operation unless practiced under very strict antiseptic conditions, it ought not to be applied in cases of peritoneal adhesions unless these cause intolerable pain.

Arterial Catheterism.

In the *Progres Medical* there is an article on this subject by Professor Severeau, of Bucharest, who says that he thinks he is the first one to propose the practice of introducing a catheter into an artery in certain cases. He has practiced it in cases of grangrene due to embolism, as an adjunct to amputation of the mortified part. The procedure consists simply in inserting a small flexible catheter (rendered thoroughly aseptic by means of alcohol and carbolic acid) its whole length into the lumen of the artery by means of to-and-fro movements. When the blood begins to flow alongside of the catheter the latter is withdrawn and clots are then ejected from the artery, so that the course of the blood circulating in it is re-established. The capillary hemorrhage from the flaps then becomes more abundant and the tissues assume a brighter hue. To this procedure the author attributes it that he has ceased to encounter gangrene of the flaps and has obtained their union by first intention. Sometimes, he says, owing to adhesions between the clot and the wall of the artery, it is impossible to make the instrument penetrate the artery, and in such cases it is not uncommon to see a portion or the whole of the flap become gangrenous.—*Omaha Clinic.*

The Operative Treatment of Ulcer of the Stomach.

At the late congress of German surgeons, Knester reported the case of a 21-year-old man who showed symptoms of ulcer of the stomach soon after straining himself severely at lifting. A year or so afterward severe hemorrhage from the stomach occurred so frequently that the patient was brought to the point of death. The much dilated stomach was opened and a deep ulcer was found on the posterior wall near the pyloric end. This was thoroughly cauterized with the Paquelin, and as no opening into the intestine could be found a wide communication between the stomach and the jejunum was made. The patient recovered completeley and is able to do any kind of work.

BACTERIOLOGY.

Effects of the Sun on Bacteria.

The recent study of micro-organisms has explained facts which we know to exist, but for which no intelligent reason could be given. The power of the sun's rays in destroying or modifying the action of many of the innumerable varieties of micro-organisms has been demonstrated in a marked degree, especially by the experiments of Dr. Palermo, of Naples. It was found that Koch's cholera bacilli, now almost universally credited with producing cholera in man, and which are fatal to guinea-pigs in about eighteen hours, if exposed to the sun's rays from three and a half to four hours, were perfectly harmless.

In these experiments another fact was brought out which may prove of great importance. It was found that guinea-pigs in whom inoculation had produced marked attacks of cholera from which they had recovered were safe against any further attack, repeated inoculation producing no effect. If this is true of the pig, why may it not hold good in the human being, the inoculation not only producing a milder form of the disease, like kine-pox, but rendering it cholera-proof?—*Med. Times.*

OTOLOGY.

The Reciprocal Relations of the Two Ears.

Dr. Urbantschitsch, of Vienna, remarks that although the relations between the two eyes, especially the so-called sympathetic affections of the eye, have long been known, those between the two ears have hitherto attracted little attention. It seems, from the studies of the author, that they may often be demonstrated, and that they are sometimes of much practical importance.

In biauricular audition it has been already observed that an ear in which the hearing is notably diminished may exercise a stimulant influence upon the other organ. The treatment of one ear augments the therapeutic effect obtained on the other even when the treatment has no beneficial effect upon the hearing of the first. One fact, especially, possesses great interest, viz.: by an operative procedure upon the transmitting apparatus of one ear we may not only arrest the diminution of hearing upon the other side, but obtain a decided amelioration and sometimes a return to the normal condition.

These reciprocal relations between the two ears, and especially the synergistic effects of accommodation, deserve attention and permit the hope that we may sometimes intervene with success—at least, in one of the ears—in certain cases of progressive deafness.—*Revue de Laryngologie.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM OCTOBER 28, 1894, TO NOVEMBER 3, 1894.

Captain Walter W. R. Fisher, Assistant Surgeon, will be relieved from duty at Fort Columbus, N. Y. H., upon the expiration of his present leave of absence, and will report for duty at Fort Meade, South Dakota, to relieve Captain Norton Strong, Assistant Surgeon.

Captain Strong, on being relieved by Captain Fisher, is ordered to Fort Sheridan, Illinois, for duty at that post, relieving First Lieutenant George J. Newgarden, Assistant Surgeon.

Lieutenant Newgarden, on being relieved by Captain Strong, is ordered to Fort Wayne, Michigan, for duty.

So much of the special order as directs Captain Ogden Rafferty, Assistant Surgeon, to report to the commanding officer Presidio of San Francisco, California, for duty, is revoked.

Leave of absence for six months, on surgeon's certificate of disability, is granted Major Clarence Ewen, Surgeon.

So much of the order as assigns Major William H. Gardner, Surgeon, to Fort Custer, Montana, is revoked.

So much of the order directing Captain Alfred E. Bradley, Assistant Surgeon, to report for duty at Fort Keogh, Montana, is amended as to direct him, upon the abandonment of Fort Sully, South Dakota, to report for duty at Fort Custer, Montana.

Leave of absence for four months, to take effect upon the final abandonment of Fort Ontario, New York, is granted Major John V. Lauderdale, Surgeon U. S. Army.

NEWS AND MISCELLANY.

New York State Association of Railway Surgeons.

Fourth annual meeting to be held in the Academy of Medicine, 17 West Forty-third Street, New York City, Thursday, November 15, 1894.

PAPERS.

1. President's address, "Important and Unsettled Questions in Railway Surgery."

SPECIAL TOPIC.

2. Shall we amputate? Or shall we wait? When shall we amputate? (*a*) "Arguments Favoring Early Amputations," by Dr. W. L. Estes, South Bethlehem, Pa. Discussion by Dr. J. B. Murdoch, Pittsburg, Pa.; Dr. J. S. Wight, Brooklyn; Dr. A. P. Grinnell, Burlington, Vt. (*b*) "Arguments Favoring Delayed Amputations," by Dr. T. M. Manley, New York City. Discussion by Dr. C. M. Daniels, Buffalo; Dr. J. S. Wight, Brooklyn; Dr. A. P. Grinnell, Burlington, Vt.; Dr. J. B. Murdoch, Pittsburg, Pa. (*c*) "Technique of Amputation," by Dr. John A. Wyeth, New York City.

3. "Asepsis and Antisepsis in Surgical Work," by Dr. F. A. Stillings, Concord, N. H. Discussion opened by Dr. A. P. Grinnell.

4. "Special Features in Railway Surgery," by Dr. C. B. Herrick, Troy. Discussion opened by Dr. G. P. Conn, of New Hampshire.

5. "The Immediate Care of Railway Injuries," by Dr. J. A. Van Duyn, Syracuse. Discussion opened by Dr. Geo. Chaffee.

6. "Important Factors in Unusual Results Following Traumatisms," by Dr. R. S. Harnden, Waverly. Discussion by Dr. P. A. Skiff, Frankfort; Dr. C. S. Parkhill, Hornellsville.

OFFICERS FOR 1894.

President, M. Cavana, Oneida; Vice-Presidents, R. S. Harnden, Waverly, C. S. Parkhill, Hornellsville; Secretary, J. B. Hewlitt, Middletown; Treasurer, J. F. Valentine, Brooklyn.

THE
MEDICAL AND SURGICAL
REPORTER.

No. 1968. NOVEMBER 17, 1894. Vol. LXXI—No. 20

ORIGINAL ARTICLES.

THE CONDUCT OF THE MEDICAL STUDENT.*

THEOPHILUS PARVIN, M.D., Philadelphia.

Gentlemen:—Let me give you hearty welcome to my lectures! Such greeting is both pleasure and duty.

But whether you have well come is a question which will be decided by each one according to his conduct during these six months of our association. If he prove indifferent to obtaining knowledge, negligent of opportunities, if wasteful of time, and, above all, if yielding to temptations to evil which so abound in a great city and appeal so strongly to young men, then he has ill come and should be condoled rather than congratulated. It is my desire in this hour to say a few words which may help, even in slight degree, to make you better students and better men, and protect you from some of the dangers which beset your path—dangers perilous alike to the physical, intellectual and moral nature.

In Swift's "Tale of a Tub" the author remarks: "The old Slavonian proverb said well that it is with men as with asses—whoever would keep them fast must find a very good hold at their ears." Every capable medical teacher desires to secure such good hold at the beginning, and keep it until the end of his lectures. Without faithful attendance upon instruction and diligent attention upon the part of students, it is the task of Sissyphus to teach and that of the Danaides to learn. The teacher and the pupil are mutually dependent—the one assists the other. Let us recognize this dependence, and pledge ourselves to common sympathy and help.

You are students of medicine, and two questions are suggested: What are students? and What is medicine? The word student, by its etymology, indicates desire, affectionate, eager, diligent application, strenuous strife and struggle. If the heavens fall we catch larks; but the heavens do not fall, and whatever good we get must be by effort, and the greater the good the greater the exertion necessary to obtain it; we must seek knowledge as one seeks hid treasure. To study successfuly means patient, persistent effort and the watchful use of time, so that no golden minutes are lost. It is said that Luther had inscribed upon the walls of his study, *Bene orasse est bene studuisse.* Do not hastily reject this assertion as the delusion of a fanatic or religious enthusiast. Remember that one of the greatest of English minds in the present century, Coleridge, declared: "Prayer is the highest energy of the human soul." The question of an objective reality corresponding to this exercise I do not now discuss, but that an important subjective influence thence results few are rash enough to deny.

Further, to be a good student there must be a sound mind in a sound body, and therefore see to it that you keep sound bodies. Unfortunately few men are so tempted to neglect the proper care of their own health of body as physicians and

*An address at the beginning of the course of lectures upon obstetrics, diseases of women and of children, Jefferson Medical College, October 4, 1894.

medical students. But you, who are future priests of Apollo, must be faithful worshipers of Hygeia. One thing of great importance in reference to bodily health is regular and sufficient time for sleep. One of our own guild, Sir Thomas Browne, has eloquently said: "Half our hours we spend in the shadow of the globe, and the twin brother of death exacteth one-third of our time." Eight hours' sleep is needed by the majority of students, and they who neglect this allotment sooner or later suffer, suffer in body and in mind; appetite and strength fail, and they lose clearness and quickness of mental vision; especially is this the case if the whole night is spent in study, working—

> "Till in the vault of heaven the stars decay,
> And the sky reddens with the rising day,"

and then snatching a few brief hours of sleep.

It is important, in studying, not to devote too much time continuously to the same subject, for, as when constantly gazing upon a single object the vision becomes confused and indistinct, so our intellectual sight is obscured by too long occupation with the same theme. It sometimes happens that one forgets a name, and the more he endeavors to recall it the more difficult and impossible the recollection; but let him cease his effort and direct his mind to something else for a time, and at its expiration it often happens that the name is recalled so quickly that the action seems spontaneous. Archbishop Whately has given this advice: "Never remain long puzzling out any difficulty, but lay the book aside and return to it some hours after, or next day, after having turned the attention to something else."

Remembering now that, as of old, much study is a weariness to the flesh and a weariness to the mind, too, exhausting it, recreation is necessary for the student, but let it be re-creation. Locke said that "whoever hopes to employ any part of his time with efficiency and vigor must allow some of it to pass in trifles." Such amusement or recreation must not interfere with the usual hours for rest, ought not to involve intellectual strain, or cause great nervous excitement, suggest impure thoughts, or excite sensual feelings, and if not always elevating to thought and feeling, at least ought never to degrade. Renan, in an address to students made not long before his death, said, "the joyous intoxication of the new wine of life, which makes you deaf to the cowardly complaints of the discouraged, is legitimate," and "the flowers have lost none of their beauty, nor the spring of its radiance." But let us remember that intoxication may bring delirium, and that swift and subtle poison may be concealed in the flower's fragrant beauty. Pitfalls for the unwary are numerous, and how many fall into them! There may be evil suggestions from companion, in the pages of a novel, or on the stage. How mistaken they are who "think that they shall taste the aconite and not die, or crown their heads with juice of poppy and not be drowsy." * So many different materials enter into that structure, personal character, which you build day by day, how watchful you ought to be that no thought or desire, no word or act of which, in the coming years, you will be utterly ashamed, make part of it. Juvenal said, *Nemo repente fuit turpissimus*, that is, the basest has not become such at once. Sir Thomas Browne expressed the same thought: "No one falls from virtue, like Vulcan from heaven, in a single day." Let the awful lapse be averted by preventing the first step.

Let us now, for a few minutes, consider the second question, What is medicine? The word is derived from the Latin word *medeor*, to cure, to heal; and *medeor* is from *madh*, which signifies to be wise, and from *madh* we have *madha*, the healing art. You thus see that, in its etymology, medicine is wisdom, not all wisdom, but a special department thereof. The essential objects of medicine are the prevention and cure of disease, the promotion of health and the prolongation of life. But what different conceptions of this department of human knowledge have been advanced by some! Thus, Swift speaks of one who held that anatomy was the ultimate end of physic, and Kilian, in the preface to a "System of Medicine," published at Jena in 1826, made this remarkabe statement: "The science of medicine does not exist in order to cure diseases, but there are diseases in order that there should be a science of medicine."

What changes in medicine and in medical teaching in this century! About a

* Jeremy Taylor.

hundred years ago Dr. William Shippen was teaching anatomy, surgery, and obstetrics in the only medical school in Philadelphia. Forty-two years ago I served several months as resident physician of Wills' Hospital, and not one member of the staff was a specialist in diseases of the eye; the staff consisted of surgeons and general practitioners, and they did their work quite as intelligently, so far as the knowledge of the day permitted, and probably operated as skillfully as the present members of the staff do. At that time there was not an ophthalmologist in the city. Now one or more ophthalmologists can be found on almost every chief street.

What changes in medical teaching in a century! How rapid the growth of specialism in forty years! These changes have greatly increased the work of medical students. The terms of instruction have been lengthened, and are one-third or one-half more, or doubled. The facilities for teaching have in all departments become greater. If you are required to study more subjects, and with more minuteness, you have a much longer time in which to do this.

While specialism is at once the proof and the power of the advance of medicine, this movement is not an unmixed good, so far as the complete and harmonious development of the doctor is concerned. A Hippocrates, a Sydenham, or a Harvey seems an impossibility in our age; with the many specialists an all-around man, one qualified to do good work in each of the various departments of medicine, will become exceptional in the cities; he will necessarily be found in the country chiefly, for the tendency now is toward not the formation of a polygonal personality, but to the making of one-sided men, or a sort of localized hypertropy in knowledge and skill. Goldsmith said, jestingly: "Is the animal machine less complicated than a brass pin? Not less than ten different hands are required to make a brass pin; and shall the body be set right by one operator?" I think the words of DeQuincey are true in regard to specialism in medicine: "This specialism is very advantageous so long as the subdividing principle does not descend too low to admit of a perpetual reascent into the generalizing principle which secures the unity of the science."

It seems to me that the analytic spirit has been carried quite far enough in medicine; and indeed it happens that one specialist sometimes invades the territory of another, and frequently encroaches upon the rights and duties of the general practitioner. Another danger arises from specialism, and that is the liability to exaggerate maladies of particular organs by the specialist, so that he may forget that there are other organs than a uterus, eye, throat, or stomach, etc., and also forget that the local disorder is, in many cases, the mere expression of a constitutional state, more appropriately treated by the family physician. So far as my observation permits me to judge, the best specialists have been those men who first spent several years in general practice.

The advance in surgery in recent years, thanks especially to anæsthesia and antisepsis, has been great and its triumphs wonderful.

Surgical operations are very attractive to students, but they are not the most important part of medical teaching. We may commend anatomical knewledge, admire operative skill, and especially be fascinated by the richer pecuniary reward which comes to the surgeon than to the physician—a gastric or intestinal catarrh requires far more knowledge and professional wisdom, and longer service, but is not half as profitable as an amputation. Surgeons, much oftener than doctors, have their achievements proclaimed in newspapers, usually without their connivance and greatly to their regret. Sometimes operations are done unnecessarily; they might have been averted by wise medical treatment, or are followed by inevitable death—a great operation, brilliant surgery, but the patient perished! I wish there were more surgeons to-day like John Hunter, who held the operative part of practice in the lowest estimation. He said: "To perform an operation is to mutilate the patient whom we are unable to cure; it therefore should be considered as an acknowledgment of the imperfection of our art." *

Concluding this topic, do not think surgery the chief thing in your studies, but

* In connection with the remark of John Hunter, we quote the following from Schopenhauer: "Our doctors have no longer the same classical culture as formerly, when it gave them a certain humanity and an elevated manner. Now they go as soon as possible to the university, where they only want to learn surgery, so that they may prosper on earth."

always let it have a much inferior position to the practice of medicine. Do not become specialists, at least, while you are students. As far as in you lies, let each be a complete man, *teres atque rotundus,* and not a local hypertrophy.

It is not the college that makes the able practitioner, but a man furnished suitable opportunities works out his own professional character, succeeding by what he is, and by the faithful use of his opportunities. The famous blue-grass pastures of Kentucky do not make the winning racer; a "scrub," though kept on them for years, will never get a prize, for, as George Eliot said, "breed is stronger than pasture."

The acquisition of useful knowledge is the chief end of medical study, and it is my strong conviction that if only such knowledge were taught by medical schools three years, the college session including at least eight months, would be sufficient for imparting it, if the students came thoroughly qualified for their study.

I have often thought that the advice of Lord Bacon might, in part, be applied to the reading of medical students: "Read not to contradict and confute, nor to believe and take for granted, nor to find talk and discourse, but to weigh and consider. Some books are to be tasted, others to be swallowed, and some few to be chewed and digested; that is, some books are to be read only in parts, others to be read attentively, and some to be read wholly, and with diligence and attention." Again, he said: "Some books also may be read by deputy, and extracts made of them by others; but that would be only in the less important arguments, and the meaner sort of books; else distilled books are like common distilled waters, flashy things." Does not the last statement seem prophetic, and have reference to the so-called medical quiz-books, the last refuge of ignoble minds about the time of examination, and in some cases, the liveliest hope of mental eunuchs for fame and fortune, place and power?

When we reflect that the most prolific producers of medical books usually are quite young, and that the motive for writing them is frequently purely selfish, we do not wonder at the multiplicity of books, most of them destined to death long before their authors. If all books, monographs, and contributions to medical journals that are essentially bids for place or practice were burned, a large amount of our literature would be gone, but in the end, while fewer books and journals would be published, they would be better ones.

In a previous part of this lecture allusion was made to special temptations occurring in great cities to young men. Among the gravest of these is that which invites to illegitimate sexual indulgence, and in speaking upon this subject plain words will be used. I trust that neither the theme nor the mode of treatment will be regarded as improper on the part of a teacher addressing medical students. Read the first chapter of Paul's Epistle to the Romans, and see how plainly sodomy and sapphism are spoken of as crimes of the day.

Professor Ribbing,* of the University of Lund, in a series of lectures to the students of the university upon Sexual Hygiene, 1889, remarked: "I do not know whether I am mistaken, but it seems to me that the sexual question is the root and the blossom, the beginning and the end of all morality." Surely, then, for your good, and for the good you may thereby be enabled to do others, a discussion of one phase of the sexual question, brief and imperfect as it must necessarily be, is right, and, I believe, needed.

Especially, as it seems to me, is there a strong demand for an exposition of what I believe the truth upon this subject, when doctrines subversive of morality, and tending to promote vice, are uttered by eminent writers, and even some members of the profession become practically advocates of prostitution. The following eloquent passage is from Lecky.† The author, after referring to the danger of "incursions of irregular passions in the domestic circle," says: "Under these circumstances there has arisen in society a figure which is certainly the most mournful, and in some respects the most awful, upon which the eye of the moralist can dwell. That unhappy being, whose very name it is a shame to speak, who counterfeits with a cold heart the transports of affection, and submits herself as the passive instrument of lust; who is scorned and insulted as the vilest of her sex, and doomed for the most part to disease and

* Professor Ribbing's lectures have been translated from the Swedish into German, and were published in Leipsig in 1892.

† "History of Morals in Europe."

abject wretchedness and an early death, appears in every age as the perpetual symbol of the degradation and sinfulness of man. Herself the supreme type of vice, she is ultimately the most efficient guardian of virtue. But for her the unchallenged purity of countless happy homes would be polluted, and not a few who, in the pride of their untempted chastity, think of her with an indignant shudder, would have known the agony and remorse of despair. On that one degraded and ignoble form are concentrated the passions that might have filled the world with shame. She remains, while creeds and civilizations rise and fall, the eternal priestess of humanity."* I shall presently quote in opposition to this view the words of an earlier, and I believe wiser, British moralist. Mona Caird† said a few years ago: "Prostitution is as inseparable from our present marriage customs as the shadow from the substance. They are the two sides of the same shield, and not the deepest gulf that ever held human beings asunder can prevent the burning vapors of the woman's Inferno which is raging beneath our feet from penetrating into the upper regions of respectability and poisoning the atmosphere."

When one of the old philosophers, Cato, I believe, was asked what he thought of usury, he replied: "What do I think of murder?" If doctors were asked what they thought of prostitution, very many, possibly the majority, would answer that it is a necessary evil; and some few would state that they prescribed illegitimate sexual indulgence for some of their patients; indeed, such advice was recently given by a contributor to an American medical journal in the treatment of onanism. Sir James Paget, on the other hand, condemns such counsel:* "Many of your patients will ask you about sexual intercourse and expect you to prescribe fornication. I would just as soon prescribe theft and lying or anything else that God has forbidden. Chastity does no harm to body or mind; its discipline is excellent; marriage can be safely waited for; and among the many nervous and hypochondriacal patients who have talked to me of fornication, I have never heard one say he was better or happier for it."

Mantegazza says:† "Do not cure onanism by prostitution, but cure the vice by virtue."

Max Simon, speaking of prostitution as a therapeutic agent, more especially in aphrodisia, remarked:‡ "Behold a new branch of therapeutics; it is pornotherapeia. Science makes the lorette prophylactic; she ought hereafter to be found in the laboratory of the pharmacist, occupying a place between phosphorus and copaiba."

Professor Ribbing, from whose work I have previously quoted, makes the following observations upon prostitution: "If we find a locality, the people having plain habits, prostitution unknown, and marriage honored, in what relation shall these institutions stand to each other? Or, observing city life, how far can we look upon prostitution as a bulwark protecting the sanctity of marriage, when we positively know that illegitimate sexual intercourse attracts and ruins in every way men in general, and especially the heads and supports of families? The plain, average woman has a clearer judgment upon this question than, for example, the fashionable society woman, for she knows that as a consequence of prostitution she runs the risk of getting a husband whose purity has been polluted, health undermined, morals lax, whose fidelity cannot be trusted, whose illusions are gone, whose love has been robbed of its youthful bloom, and last, but not least, she is exposed to the terrible danger of bearing diseased children, or those in whom the excessive sexual passion is inborn, inbred. The

* Lecky's opinion as to the value of prostitution is alluded to by Grant Allen in the concluding lines of his brief poem, "Sunday Night at Mabille, Second Empire," a poem which vividly pictures the wretchedness and ruin of prostitutes:

"Why have I brought you then to see Mabille
This Sunday night? you ask.—To find my text
And point my sermon. Here you have its gist:
—You tell me we must shut our eyes to all
That turns this gaudy Mabille to a hell,
If we would keep our wives and daughters pure.
So be it: I know not. But if we must hold
So many hearts in anguish and despair,
So many lives that once were blithe and free
In tenfold slavery, to guard the rest
From slight taint of ill; then, staring round
At all the hapless forms that crowd Mabille,
And knowing all that we have seen and said,
And feeling all this life in need of change,
One question ever rises to my lips,
One question that I scarcely dare to breathe—
If woman's virtue cost so much to keep,
Good friend, is woman's virtue worth the price?"

† *Westminster Review*, November, 1888.

* "Clinical Lectures and Essays."
† "Hygiene de l'Amour."
‡ "Deontologia."

mother knows that prostitution is a constant danger for growing sons, and threatens the worst disappointments and sufferings for their daughters when they marry. Indeed, I cannot see that we owe anything to prostitution. Is the sexual intercourse simply animal, without personal love, and robbed of family ties and natural responsibility, he soon becomes unsatisfied with common means, and extraordinary excitements are necessary, and thus the *blasé* requires something new, and even little girls may become his victims." "I have never looked upon prostitution for one moment as a necessity or a good, or as a protection of domestic virtue; the more it develops the more it harms married life, the protection of humanity."

Let me reinforce these words of Ribbing by the opinions of Dr. Samuel Johnson. When Boswell said to the latter, "So, then, sir, you would allow no irregular intercourse between the sexes?" Johnson's reply was: "To be sure I would not, sir. I would punish it more than is done, and so restrain it. In all countries there has been fornication, as in all countries there has been theft; but there may be more or less of one as of the other, in proportion to the force of the law. All men will naturally commit fornication as all men will naturally steal. And, sir, it is very absurd to argue, as has been often done, that prostitution is necessary to prevent the violent effects of appetite from violating the decent order of life, nay, should be permitted in order to preserve the chastity of our wives and daughters. Depend upon it, sir, severe laws, steadily enforced, would be sufficient against those evils, and promote marriage."

Of course, the essential causes of prostitution are the uncontrolled passion of men and the poverty of women.* But these are assisted greatly by the judgment of society, which regards a man's lapse from virtue as venial, while, if a woman falls, she becomes a pariah, an outcast. Sir Herbert Maxwell remarks† that "from the day a boy goes to school he is aware of the existence of a certain kind of evil of which a girl never suspects the existence until she has grown up. The boy knows it is evil, but in the eyes of the world there is no disgrace in yielding to it, and public opinion condones it. Unless he is of peculiar constitution it occupies a great deal of his thoughts." The writer further states that this is the most important circumstance in modern society which "completely severs the outset in life, and separates the tone of mind in the two sexes." While conceding the truth in chief of these statements, we can hardly believe young girls are quite as ignorant of sexual irregularities on the part of men, for even if female servants give them no information, the daily paper often does—indeed, sometimes a popular newspaper has thinly disguised advertisements telling where prostitutes are found. Is it right that there should be the barrier referred to between the sexes? Man's want of chastity has erected it, and man's restoration to purity must cast it down.

Why should there be two standards of morality in this matter, one for men and the other for women? "If chastity is a law for women, it must be a law for every woman; and if it is a law for every woman, it follows, necessarily, it must be for every man." A man, when he marries, desires first and exclusive possession; he does not select his bride from among prostitutes. But has he any right to demand a purity on the part of that bride which he cannot give? Women are themselves chiefly to blame when they marry profligates and debauchees. But the guilt belongs also to society, which so kindly condones the offenses of such men, receives them with open arms into its charmed circle, when it would be horrified to look upon the female companions of these men in orgies of lust—nay, a poor Magdalene turning her back upon her infamous life, and trying to make an honest support, could not have a menial's place in the kitchen!

Wise opinions and judicious counsels on your part may do much to lessen this great evil of the ages, while your own lives of continence will give additional strength to your efforts in accomplishing this end. In Wagner's "Parsifal" the story is told of a king who is suffering from a wound the efforts to heal which have been vain; but promise is made that the wound can be healed by "a pure being whose simple soul has been rendered knowing through pity." *Parsifal*, who

* What would you think of the employment agent of a store making the infamous suggestion to a young lady who remonstrates against the small compensation offered for her services, truly saying she could not live on it: "You might get a friend to pay your boarding?"

† "The Conduct of Friendship," *Nineteenth Century*, 1893.

has been tried, but successfully resisted sensual enticement, tearing himself from the embrace of the temptress *Kundry*, comes to the king who has heard the prophecy—

> "In the loving soul of a guileless one
> Put thy faith; him have I chosen."

The wound is healed. Are there no Parsifals here who may help bring blessed healing to this sorest wound of society?

I know that many of you will be tempted to evil, and I fear some may fall, and therefore I urge most earnestly such arguments as I can against this black vice. Prostitution more than brutalizes women; it is a market of human flesh and blood, yea of human life, for disease and premature death are almost inevitable to prostitutes. The law of Sperck is that the prostitute is attacked with syphilis in from one to three years after she begins her wretched trade. She perpetuates gonorrhœa and syphilis. She is doomed to jail, or hospital, or the grave, after a brief career. Yet the accursed trade is licensed in many countries, and some would have it licensed here. A distinguished French author,* referring to the licensing which exists in his country, observes that he is "convinced these regulations are without utility, both in regard to health and morals, and that they will always remain insufficient, no matter how severe." Think of France with its natality scarcely more than its mortality, and three millions of its thirty-six millions of inhabitants bastards, when even the suggestion of adopting the license system is made. Prostitution necessary? In Paris, and doubtless everywhere else, the prostitute's most lucrative time is just after workmen and laborers are paid. Pecuniary restraint proves moral restraint—the need ceases if there is no money. Whenever hard times come prostitutes complain that their business is poor. If poverty makes men even temporarily virtuous, might not the absence of temptation, and a healthy public sentiment, be equally potent, and permanently potent?

Is it not loathsome to think of one of these poor creatures,† living upon the lust of men, submitting to the embraces of half a dozen or more in a single night—as fast as the supposed "excremential need" of one is satisfied, starting out with freshly painted cheeks and perfumed handkerchief, to find some new sufferer from tumid testicles, plethoric purse and lecherous lunacy? Prostitution is a horrible trade, it is a fruitful source of disease, a hot-bed of venereal affections, and sinks all participants in lower depths of degradation.

The certificates from doctors, whether appointed by government, or volunteers, who for paltry pay open wider the doors of illegitimate indulgence by taking away, or lessening the fear of infection, are often, usually indeed, not worth the paper upon which they are written, as securing probable immunity from disease.

In Berlin there are eight thousand licensed prostitutes and thirty thousand clandestine ones. I recently asked a medical acquaintance in that city whose practice is largely in venereal diseases, by which class his male patients were more frequently infected, and his reply was by the former.*

Lord Bacon said: "Nuptial love maketh mankind; friendly love perfecteth it; but wanton love embaseth it." There can be only evil from prostitution. I read in a medical journal some time ago, a quasi-justification of the wickedness upon the ground that prostitutes were deficient in cerebral development. The rape of an idiot does not make a man nobler.

Prostitution prevents the normal growth of population, for it sterilizes thousands and tens of thousands of women who are its victims; it delays or prevents marriages, and when men who have been engaged in debauchery turn from their dissolute life and marry, they may carry disease to the nuptial couch, so that their wives are sterile or give birth to syphilitic children.

How can the former companion of prostitutes have a true conception of a pure, virtuous woman, and know the ideal of loving, sacrificing womanhood? He must

* Thulie: "La Femme."

† "How miserable is the condition of a courtesan whose business it is to soothe, suffer and obey the dictates of rage, insolence and lust."—Smollett in "Roderick Random." For a few years I have been greatly interested, and participated in what is known as "Rescue Work" in Philadelphia, and my pen is powerless to picture the horrors and loathsomeness of prostitution, as I know it from personal observation, and the histories given me by some of its unhappy victims.

* Possibly licensed prostitutes are more sought after, have a larger number of visitors, because of the fancied security from becoming infected furnished by authorized professional examinations, and hence are more liable to disease. Or, possibly, the experience was exceptional, quite accidental. But this one thing is evident, on account of it I have quoted the statement, the examination by police surgeons in Berlin fails to secure to those who visit licensed prostitutes immunity from venereal disease.

fail in what De Quincey has given as the true criterion of manhood, "the reverential feeling sometimes suddenly developed toward woman, and the ideal of woman. From that moment when women cease to be regarded with indifference, and when the ideal of womanhood, in its total pomp of loveliness and purity, dawns like some vast aurora upon the mind, boyhood has ended, childish thoughts and inclinations have passed away forever, and the gravity of manhood, with the self-respecting views of manhood, have commenced."

It is a dangerous and utterly false notion that a young man may sow wild oats, and not be compelled to garner the product of his sowing. It is forever true, certain as God's law, fixed as God's throne, whatsoever a man soweth, that shall he reap.

But some one may say, I do not propose to lead a dissolute life, and a single indulgence is not a matter of any consequence.

Only once! That single offense may bring you the curse of foul disease, while another escapes after a hundred transgressions. Only once! Will it be but once? Recall the wild bird that has just had its freedom restored, attempt by kind caresses and winning words to restrain the fierce passion of the tiger that has tasted human blood. As of old, *Facilis descensus Averni.* The first step in the downward road makes the next much easier—the very fact of yielding once weakens moral power, and the second surrender is more probable than the first, and thus on and on, and who can tell where or when the series will end? Only once! A single trial of the force of Niagara's current may sweep you to swift death. Only once! You are spending your summer at the seashore, and are told of the terrible under-tow at some bathing-places, and are warned; but you would just once find out for yourself how strong this secret, subtle power of the sea is, and possibly not until that sea gives up her dead will your burial place be known. You are ascending the Alps, and have come to a dangerous and difficult pass, on the one side a profound abyss, on the other a perpendicular wall of rock or of ice, the path too narrow for turning, too slippery for any but a firm and cautious foot; only once, you say, let me pause to pluck a flower at the edge of the path—the flower is won, but you perish.

Let us cast aside these arguments and admit that there is but one sin and no plain evil from it. But has it caused no hidden and lasting injury? Few in adult life who do not have upon fingers or hands the scars of wounds received in childhood by the careless use of knife or hatchet; the wound healed kindly, but the record, it may be only a faint white line, abides, and there it is until your body and members are dust and ashes: the scar disappear!

> "Never, though your mortal summers to such length of years should come
> As the many-wintered crow that calls the clanging rookery home."

May there not be scars upon the soul more lasting even than those of the body? No wrong act can be done by man or woman that is not an injury to the actor, and that does not carry with it a penalty. In this world's economy wages are not paid every Saturday night. The memory of an evil deed and its marring cannot pass away. The flood of penitential tears cannot wash away the record, the damned spot will not out. A Swedish writer has said that society is a ship, there is a corpse in the hold and that corpse is prostitution, it cannot be thrown overboard. Every violation of virtue, every sacrifice of chastity is a corpse, and the transgressor cannot throw it overboard.

In one of Robert Browning's shorter poems he speaks of the Morgue at Paris, and the poor victims of suicide taken from the Seine exhibited for recognition, lying extended each upon a copper table; in regard to one he says:

> "Oh, women were the prize for you!
> Money gets women, cards and dice
> Get money, and ill-luck gets just
> The copper couch and one clear nice
> Cool squirt of water o'er your bust,
> The right thing to extinguish lust."

Suicide the end of lust! Do medical students ever thus perish? There stand vividly before me now two students to whom I lectured; one, thirty years ago, committed suicide because of departure from virtue. He had both wife and children. In an evil hour he went to a house of prostitution, was infected with syphilis, and a few days afterward, about the time he should have returned home at the close of the session, took a fatal dose of poison. The other referred to I knew very well and thought him safe from temptation, he was so amiable and gentle

and apparently steadfast in virtue. He graduated, had hospital experience, entered upon practice and succeeded. But unfortunately he had become infatuated with a prostitute in his hospital life and soon financial ruin came; he died by his own hand. With these facts vivid in my memory, do you wonder that I press the question of personal purity upon you so earnestly? These dead men are speaking to you by me.

How are you to be saved from immediate and imminent perils? First, abstain from alcoholic liquors. Sometimes it is true they make men "wanton as a satyr and impotent as age." But let me narrate the following incident that occurred to me more than forty years ago, as showing how intoxication may lead to lustful indulgence: One day a gentleman who had been a college friend for a year—he was much older than I and graduated three years earlier—stated that he had just returned from New York, and while there dined, together with several others, with Captain ——, commander of one of our war vessels, who had made himself famous by bombarding a foreign seaport in vindication of our country's rights, but I shall mention neither the name of the vessel nor of the captain. My friend said: "After we had been drinking wine very freely one of the company proposed that we should visit a house of prostitution; about half the number went, I among them. I certainly would not have gone if I had not been drinking. I am afraid I have syphilis." Upon examination I found he had nothing but an eruption of herpes upon the glans which would be cured in a few days. His mind was greatly relieved, especially as he had a wife.

You will frequently find in your professional experience the story of my friend repeated; that is, men will explain exposure to venereal disease by their being drunk. What relation does alcohol bear to lust? In moderate quantities the former may excite the latter, but chiefly alcohol blunts the moral sensibility, hushes the voice of conscience, and thus conduces to crime. Let the young man beware of intoxicating drinks, if for no other reason than by abstaining from them the temptation to unchaste conduct is lessened.

Further, let him beware of novels, plays, pictures that invite sensual feelings, or thoughts, and above all, of the images of lust which an idle mind is in such danger of conceiving—avoid every object or thought that may excite sensual desires. He needs especially to remember the Divine command, "Keep thy heart with all diligence, for out of it are the issues of life;" there are no words of sage or philosopher comparable to these in value. As you ascend the Rhine by steamer, possibly about half way between Mayence and Cologne, there is seen on the right a steeply rising hill on which, and in the waters at its base, there once lived a water-nymph of enchanting beauty and song, Lorelei; the young man who, intoxicated by her beauty and the music, sought near approach to the charmer, perished in the treacherous waters. There are Loreleis elsewhere than on the Rhine, and the lesson is essentially the same.

Let us find counsel in the conduct of Ulysses when exposed to the temptations of the Sirens. Listen to the story as told in Bryant's translation of the Odyssey. Ulysses, with his companions freed from the power of Circe, is about starting home, where the faithful Penelope, model of wifely love and patient sacrifice, has waited his return for near a score of years. Circe instructs him as to the perils to which he will be exposed in his homeward journey, and the means of avoiding, or of overcoming, thus referring to the Sirens:

"Thou first will come
To where the Sirens haunt. They throw a spell
O'er all who pass that way. If unawares
One finds himself so nigh that he can hear
Their voices, round him nevermore shall wife
And lisping children gather, welcoming
His safe return with joy. The Sirens sit
In a green field, and charm with mellow notes
The comer, while beside them lie in heaps
The bones of men decaying underneath
The shr veled skins. Take heed and pass them by.
First fill with wax well kneaded in th e palm
The ears of thy companions, that no sound
May enter. Hear the music, if thou wilt,
But let thy people bind thee, hand and foot,
To the good ship, upright to the mast,
Let them be charged to bind thee yet more fast
With added bands."

Let your ears be deaf to the music that lures to destruction, your eyes be blind to the beauty or Lorelei or Siren, and duty, purity, and love make a triple cord, not easily broken, defying the strong wave of temptation, and unconsumed by the fire of lust.

Let me counsel you with some of the words used by Ruskin to a young man, one of his students: "No reasoning or

resolution will stand. To turn away the eyes and thoughts is the only way. If you have not hitherto been enabled to do this, you will find in perfect chastity of thought and body, there is indeed a strange power, rendering every act of the soul more healthy and spiritual, and giving a strength that is otherwise unattainable."

Nay, more, I would quote another great English author, Dr. Samuel Johnson, and his words refer not only to the special topic before us, but also to the control of all inordinate desires: "To deny early and inflexibly, is the only art of checking the importunity of desire, and of preserving quiet and innocence. Innocent gratifications must be sometimes withheld; he that complies with all lawful desires will certainly lose his empire over himself, and in time either submit his reason to his wishes, and think all his desires are lawful, or dismiss his reason as troublesome and intrusive, and resolve to snatch what he may happen to wish, without inquiring about right and wrong." "No man whose appetites are his masters, can perform the duties of his nature with strictness and regularity; he that would be superior to external influences must first become superior to his own passions."

Walter Scott thus speaks, in the introduction to "Guy Mannering:" "He suffers from the awakening of those harpies, the passions, which have slept with him as with others, till the period of life which he has now attained. Better, far better that they torment him by ungrateful cravings, than that he should have to repent having satisfied them by criminal indulgence."

What more shall I say? What stronger plea can I make? By the honor you bear your father, or his memory; by the love of your mother, the purity of her womanhood, and by her blessed prayers which are hanging like good angels over your head; by a sister's farewell kiss, never let your lips be polluted with a courtesan's caresses, but make chastity the law of your life. Nay more. In the name and behalf of her who some day shall be nearer and dearer than father, or mother, or sister, I beseech you remember the words of King Arthur in Tennyson:

> "To lead sweet lives in purest chastity,
> To love one maiden only, cleave to her,
> And worship her by years of noble deeds,
> Until they won her; for indeed I knew
> Of no more subtle master under heaven
> Than is the maiden passion for a maid,
> Not only to keep down the base in man,
> But teach high thoughts, and amiable words,
> And courtliness, and the desire of fame,
> And love of truth, and all that makes a man."

CONTUSION OF THE BRAIN.

J. B. MURFREE, M.D., Murfreesboro, Tenn.

The brain, the seat of the mind, is that portion of the cerebro-spinal axis contained within the cranial cavity and firmly environed by several bones of the skull.

It is composed of a white, soft substance divided into different compartments and processes, the whole being enveloped and protected by the three membranes, pia mater, arachnoid, and dura mater.

Situated at the upper extremity of the body and inclosed in a bony cavity, it is the seat of the high mental faculties which distinguish man as a rational and intelligent being; yet it, like other parts of the human body, is subject to injuries from external violence.

The injuries of the brain are usually recognized as compression, concussion, and contusion and laceration.

Contusion of the brain is the particular lesion which I desire to briefly consider. Concussion and compression of the brain are injuries that are distinct in their symptoms and generally easily recognized (though not always clearly differentiated) and are clearly and fully described in our text-books. But contusion, although a special injury distinct and separate from compression and concussion, is not always recognized, nor is it clearly and definitely treated of in our literature and text-books. Yet that such a condition does occur as a distinct pathological lesion giving rise to a particular train of symptoms is demonstrated by post-mortem examinations and clinical observations.

In a somewhat limited clinical experience I have had opportunity of observing

a train of symptoms following injuries of the head which fully conformed to those of contusion of the brain as described by the few authors who have written about this lesion.

Contusion of the brain is defined to be a sudden and violent attrition of a portion of its substance, attended with more or less laceration and an effusion of blood, generally in the form of minute specks or little clots; a sudden and violent shaking up of the brain, with a bruising of its tissues and laceration of the minute blood-vessels. In a few words, it is a bruising of the brain which (as in other parts) is followed by a certain train of symptoms indicative of the particular pathological lesions.

The most usual seat of the injury is about the base of the brain, most frequently in the cerebrum and on its under surface. The cerebellum, pons, crura, and medulla are sometimes contused, though rarely.

The extent of the injury varies, from a small patch so minute, perhaps, as to make no impression upon the individual while living, and scarcely to be recognized after death, to a contusion so extensive as to involve the greater part of an entire lobe or even one of the hemispheres. Contusion of the brain occurs sometimes with a fracture of the skull, and is then apt to be severe, and especially is this the case when the fracture is situated at the base of the brain from force applied to the vertex, as falls upon the head. Occasionally the force is so great that a contusion is produced in different parts of the brain remote from each other.

The cause of contusion of the brain is always external violence, either directly or indirectly applied. In severe cases the lesion is usually produced by direct violence, while the milder cases are the result of indirect violence. Sometimes, however, though rarely, a severe contusion may be the result of indirect violence. Contusion of the brain occurs in two different forms, the circumscribed and the diffused.

In the circumscribed variety the injury is limited to a small portion of the brain and is confined to the gray substance.

The amount of the injury to the brain varies in degree and extent. In the milder cases of these injuries the contusion is of small area. At the seat of the injury there is a discoloration of the brain tissue; it presents a dark purplish hue and is covered with very small spots of extravasated blood (perhaps not larger than a pin's point) closely grouped together, the dark color gradually fading from the center to the circumference as the points of diffused blood become less frequent. These patches are not easily washed away, and retain their color and consistency even under rough handling.

In more severe cases the central parts of the bruised portions, thoroughly infiltrated with blood, are of a uniform dark purplish color, which extend some distance both into the gray and white substances; imbedded in this part are little clots of blood of the size of peas and around the circumference and in the deeper parts are specks of extravasation scattered more and more widely until they gradually disappear. The brain substance, torn, broken up, and shreddy, readily gives way under a gentle stream of water, which, while gradually loosening the clots of blood, carries them away, leaving little pits with irregular and shaggy margins and thickly studded throughout with pin-point extravasations.

In contusion of the brain the membranes are also involved to a greater or less extent. In the mild cases the pia mater only is injured. In the severe cases the investing membrane as well as the pia mater is torn and there is an extravasation of blood in the cavity of the arachnoid. In the diffused variety there is a general contusion of the brain; the extravasation of blood is more generally scattered throughout the brain, on the surface as well as in the interior.

Circumscribed contusion is of more frequent occurrence than the diffused variety. Contusion of the brain may take place at the point where the blow is received, or it may be far away, at a part distant from the seat of the external wound; on the opposite side of the brain, by *contre-coup*, "the wave in the cerebro-spinal fluid created by a blow produces what is often its maximum effect on the opposite side of the skull from the point struck, tearing the vessels of the pia mater and cortex."

All parts of the brain are not alike subject to contusion, the lesion occurring in some parts more frequently than in others.

The base of the brain is most frequently

the seat of the contusion, the upper part very seldom. The middle lobes are most frequently injured, the anterior next and the posterior very seldom.

This is explained by the fact that the posterior lobes lie upon a soft cushion, the tentorium cerebelli, but the anterior and the middle lobes are in contact with irregular and angular projections of bones, which, although rounded off to a certain extent and smoothed down by the dura mater, are still both sharp and numerous.

The cause of contusion of the brain, as already stated, is external violence upon the head, especially with a blunt-pointed instrument. It is the result of a concentration of force applied to one particular part. The skull need not be fractured, and, as a fact, in a majority of cases there is no fracture. Occasionally the contusion is the result of violence indirectly applied to the brain, as from falls upon the feet, etc.

The symptoms of contusion of the brain are always meager, often obscure, so much so that the nature of the injury is frequently overlooked, necessarily so from the fact that contusion is nearly always associated with concussion of the brain, and the symptoms of each lesion are so mingled and coupled together that the diagnosis is uncertain, often impossible for the first few days of the injury. Again, contusion in some cases is complicated with fracture of the skull, and then compression of the brain masks the symptoms of contusion.

Ordinarily, the particular train of symptoms which indicates contusion of the brain is: persistence of unconsciousness, stupor without stertorous breathing. In milder cases there is a contraction of the pupils of one or both eyes (usually only one), contraction of one of the lids, convulsive movements of one or more of the muscles of the face, especially about the lips; difficult pronunciation, loss of expression, a vacant stare. In addition to these symptoms, in the severer cases there will be tonic spasms of the limbs, restlessness and extreme agitation, constant rolling and tumbling in bed, unconsciousness, partial or complete; rigid contraction of one or more of the limbs, especially the fingers; drowsiness and more or less delirium.

In the slight cases the symptoms will be less marked and evanescent, the brain in a short time accommodating itself to the injury. The decubitus is decidedly symptomatic, the patient almost invariably lying upon one side with the limbs drawn up; there is a general flexion of the limbs. The limbs are flexed, and if straightened out are immediately drawn up.

In some cases there is a relaxation of the sphincters, the urine and feces passing involuntarily; in one case there was retention of the urine. There will be pain in the head (generally constant) with a partial paralysis of some of the facial muscles, impaired vision, twitching of the muscles of the face, defective sensation with mental hebetude.

The diagnosis in well-marked cases will not be difficult: the persistence of stupor, the absence of stertor, the great restlessness, the peculiar decubitus, the impaired mental action, together with severe pains in the lower limbs, point clearly to the nature of the disease.

But in mild cases these symptoms are insignificant, and often many of them are entirely absent. When contusion is complicated with compression of the brain we have no means of estimating the extent of each lesion nor of differentiating them.

The prognosis in contusion of the brain is dependent to a great extent upon the character and condition of the patient, the amount of violence used in producing the injury, the extent of the lesion, and the existing complications. In slight contusion of the brain of the young and healthy, uncomplicated, the prognosis is very favorable; the effused blood is readily absorbed and the injury of the brain tissue repaired. In the aged and cases where the injury is great and the contusion extensive, the prognosis is unfavorable. Contusion of the brain is a very dangerous condition, oftentimes attended with fatal results; but it is not always fatal—oftentimes the patient recovers. But when the contusion is very great the worst consequences are to be feared; death may result soon after the reception of the injury, from structural lesion of the cerebral tissue, or occurring later, may be caused by inflammation of the brain and its enveloping membrane.

The course of the pathological changes consequent upon the injury is usually prolonged for several days. The active symptoms may continue for weeks or more when, in favorable cases, there is a gradual return of the mental faculties and a

subsidence of the graver symptoms, yet for many weeks the effect of the injury is felt by the patient. He suffers with severe and frequent-recurring headaches, indifference, with an indisposition to make any mental effort.

The results of the injury are pains in the lower limbs, especially about the knees, peevish disposition, mental hebetude and cerebral irritation.

The treatment of the contusion is one of expectancy more than of active medication. There is always more or less shock, and the first indication is to secure a gradual reaction. The patient should be placed in a recumbent position, ample ventilation secured, and utmost quietude enjoined; artificial heat to the extremities and diffusible stimulants administered, hypodermatically if need be.

After reaction from the shock it is absolutely necessary to keep the patient perfectly quiet and at complete rest. The excessive restlessness must be controlled by anodynes, and the best of these is morphine hypodermatically administered. No fear need be felt of increasing the tendency to inflammatory action by the use of morphine. The obtunding of the sensitiveness of the nerve centers by morphine rather retards than excites inflammation. An active cathartic should be given soon after the injury; subsequently the bowels should be moved by an enema; while the diet should be light yet nutritious.

The principle of treatment is to place the patient in the best condition for the gradual restoration of the brain to the performance of its normal functions. And we can only do this by securing quietude and rest, maintaining the natural functions of the body and waiting the results, in the mean time warding off any threatened danger by appropriate remedies. Should inflammation occur it must be controlled by arterial sedatives, blood-letting (when admissible), aconite, veratrum viride and the local application of cold. The bichloride of mercury and the iodide of potassium should be given to cause the absorption of the cerebral effusion. Should the inflammation be localized and abscess result, the proper remedy would be to open the skull and evacuate the pus. The less dangerous symptoms are to be treated by the same watchful care, perfect rest, and the avoiding of any mental excitement.

COMMUNICATIONS.

FOUR ABDOMINAL SECTIONS FOR PELVIC AILMENTS.*

I. N. BRAINERD, M.D., Alma, Mich.

It is quite the custom to report cœliotomies made for ailments in the female pelvis in the section on gynæcology; but we are surgeons and the whole field is ours. If we relinquish the pelvis to the gynæcologist, the eye to the oculist, the ear to the aurist, the rectum to the "orificial surgeon," the genitals and bladder to the genito-urinary surgeon, the feet and legs to the orthopœdic surgeon, and the toes to the chiropodist, we shall soon have but an empty name.

Since our last meeting I have made four abdominal sections for ailments occurring in the pelvis of the female, as follow:

Case I.—Mrs. F., of E., Mich., aged about twenty-five. This patient had a miscarriage at eight months. Nothing threatening occurred for the first week or ten days. Then a fever reaching 105° F. developed, accompanied by rigors and other signs of sepsis. A consultant was called, who diagnosed ague. Five weeks after confinement I was called to see her. She was very low; unconscious most of the time; pulse rapid and feeble; greatly emaciated, having rigors about every four hours; was tender in the groins and in the vault of the vagina; was tympanitic and had that smoky-yellow hue so common in septicæmia. At this time the temperature was but little elevated. I diagnosed sepsis from salpingitis and pelvic peritonitis. After I had been there a short time, she roused up sufficiently to know that I was there and desired me to see her back. It was literally covered with syphilitic ulcers.

* Trans. Michigan State Medical Society, 1894.

The attending physician, whose name I am compelled to suppress to keep secret the name and address of the patient, and I then withdrew for private consultation. Several questions confronted us. The first one was ethical. The husband had married this woman less than two months before upon the supposition that he was the father of the unborn child. His utmost acquaintance with the woman had been but five months. The child proved to be an eight-months fœtus. This was the man's first pain. Now we questioned as to whether we should inform him that his wife was also syphilitic and run the further risk of raising a domestic tempest. We decided to tell him for his own protection and because it cut some figure in the prognosis.

The next question related to the advisability of an operation. She was profoundly septic, and during that day had been unconscious about half of the time. Almost nothing could be hoped for, and yet that was the only thing that offered any hope. Without the operation she must die within a day or two. I believed that the tubal trouble was subsiding and that the sepsis arose from the absorption of soiled serum in the peritoneal cavity. The attending physician had reached this conclusion before. We therefore decided to advise a section to irrigate the peritoneal cavity. We first admonished the husband of all the dangers of the operation and told him that there was but shadowy hope that it would do any good. We also advised him to consult the girl's parents, who lived but a few miles away. He did so, and the next morning reported their acquiescence.

The patient was still more feeble this morning and had been unconscious since midnight. The husband wishing the operation, however, hurried preparations were made and the operation was done. The patient had been moribund for two hours. She needed no chloroform. Her pulse was so weak we injected strychnia in aromatic ammonia. When the incision was made bloody and stinking serum boiled out. Copious douching with aseptic hot water cleansed the cavity. The patient was quickly bandaged and put to bed in better condition than she was in when she was put upon the table. There was no shock. The pulse and respiration were good for about two hours, when both rapidly failed and the patient died.

This operation would not have been undertaken at all except for the fact that sometimes a patient moribund from sepsis does revive after removing the cause.

Case II.—Mrs. W., Alma, Mich., aged thirty six; my patient. For several years this lady had been an invalid and had often suffered exacerbations of pain accompanied by hysterical manifestations. About a year before the date of the operation the patient came into my hands, though I had known of the case for several years before. She then had a retroversion, with great tenderness in the region of each ovary. I replaced the uterus and put in a Smith's pessary. I suggested an oöphorectomy at that time, but the pessary did so much good that nothing further was done about it. She wore the pessary half a year, when it was removed. In another half-year another paroxysm of suffering came on, soon after a fall from the doorsteps. I replaced the pessary. After a fortnight I had to remove it because it caused so much pain. I simply removed it, but made no exploration. The patient continued suffering almost intolerable pain, until I was called to replace the pessary, because the patient suffered more now than before. This time I explored the vault of the vagina. And now, besides the ovaritis, there was a prolapsed ovary (right), and so tender that I could do nothing without chloroform. I again advised an oöphorectomy. The next morning they engaged to have it done, and the next morning thereafter it was done.

In making the incision, when I came upon what I supposed to be the peritoneum, I cautiously picked it up and cut through it. Then I came into a layer of vascular fat, and concluded that that shiny membrane was not the peritoneum. Soon I came upon another serous membrane. I cut into this and found it very thick. I kept cutting cautiously, when suddenly I found that I had "cut a gut." I had made a hole an inch long into the bowel. Now it was all plain. That first shiny membrane was the peritoneum. The layer of fat was the omentum. The next shiny membrane was the inner side of the omentum and the gut, all grown together by inflammatory adhesion. I sewed up the enterectomy with two rows of Lembert sutures, then peeled off the omentum downward for two inches, when I came into the peritoneal cavity. The wounded gut was carefully held out of the way all

the time. It was quite difficult to get up the ovaries, because of the adhesions. Both were cystic, one being nested with a score of cysts from one-sixteenth of an inch to one inch in diameter. The other contained an apoplectic clot.

This patient had vomited a great deal before the operation, and this was the greatest difficulty afterward for two or three days. Aside from this the recovery was uneventful. The temperature never touched 100° F. but twice, and then just before defecation. The wound in the gut never gave any trouble. The patient has been perfectly comfortable ever since. She now does her own work, including washing, ironing and dressmaking, and is so fat that she can hardly get into her former clothes.

I must say that I was surprised at the condition of this woman's abdominal and pelvic viscera. I did not dream that she was so great a sufferer as the operation disclosed. Because of her hysterical conduct I had but little sympathy for her. The only friend that was left her was that good old mother of hers. She was always faithful and sympathetic.

CASE III.—Mrs. V., Clare, Mich., aged thirty-six. Upon this woman I did Tait's operation for the arrest of an uterine fibroid. The recovery was rapid and uneventful, except the formation of a mural abscess. On the eleventh day the patient sat up, on the twelfth day she was around the house, and on the thirteenth day she rode thirty-five miles by rail to her home. She is doing almost a man's work. I have both her ovaries and both her tubes in a bottle; yet this woman is menstruating every twenty-eight days.

CASE IV.—Mrs. W., Holly, Mich., aged about thirty. This woman was first troubled with vomiting of pregnancy. If I am correctly informed by the patient, the vomiting was never extreme and never indicated an abortion; yet this was the first and persistent advice of her physician. At last she unwillingly consented to it. The abortion was induced and salpingitis followed. As I had formerly been their medical adviser, they wrote to me about the case. I shall not detail the symptoms as they gave them to me, but simply say that I diagnosed salpingitis and tentatively advised an operation. They wrote to me to come and do the operation. I went. The attending physician did not agree with me as to the need of an operation. We fooled away the day as they do in Congress, and I went home. In a few days they sent for me again, but I found the patient so much improved that I believed she would get along without an operation. Soon she got worse and they sent for me again. I took Dr. Day, from Bannister, with me and operated.

This proved to be the worst case I had ever seen. Two knuckles of small gut were adherent to the uterus. The cæcum and appendix were adherent to the right tube and broad ligament, making it impossible to get up the tube. I could not even get it into the wound for drainage, so I pushed the uterus down into the pelvis with one hand and pushed a finger of the other hand into the uterus, and manipulated the tube until the contents came through that way. Then I sewed up the wound and wished for much, but hoped for but little.

The tube continued to discharge for some days and gave no great trouble for three months, when the patient wrote to me saying that it was paining her again. That has since subsided and the patient is now doing her work.

In the course of her convalescence the patient was attacked with a severe ophthalmia with blepharospasm and supraorbital neuralgia. I believe that this, as well as the salpingitis, was a resultant of the ill-starred abortion.

If it be asked why I did not attempt to drain the pus-tube through the vault of the vagina after failing to get it up into the abdominal wound, or why I did not aspirate through the ventral wound, then incise and stuff with iodoform gauze, all I have to say is, I succeeded in draining by the natural way and escaped the danger of soiling the peritoneum from above and of puncturing the gut from below.

These four operations were done for causes as follow: The first one was for peritonitis; the second for diseased ovaries; the third to arrest the growth of an uterine fibroid; the fourth for pyosalpinx. I want to say that I believe that sections for salpingitis should be done more frequently than they are. Within two years I have seen two women die from salpingitis: one following labor and one whom, for charity's sake, we'll presume to have been a virgin. I saw another come very near death from an abortion, and know of another who has been laid up with it for five months and is now at death's door. These

cases were all in other towns. In the first case an operation was refused; in the second case no operation was advised because the patient was so nearly dead; in the third curetting was done because the endometritis was the worst feature; in the fourth case the patient still declines an operation, preferring to die with a putrid tube than to live without any. Her wishes will probably be gratified.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

COAL TAR IN CERTAIN SKIN DISEASES.

Dr. L. Leistikow (*La Semaine Medicale*, No. 59, 1894) claims that coal has the advantage over wood tar, oil of cade, etc., of being more powerful and having a more lasting action in pruritus and other itching affections. It is an excellent remedy in dry eczemas of the hairy scalp, back of the neck, thorax, external genitals, abdomen and extremities, as well as in Hebra's prurigo, trichophytiasis and psoriasis, especially when the psoriatic plaques are situated upon the hairy scalp, elbows and knees. Yet as this drug might give rise to symptoms of poisoning if applied to vast surfaces, its use should preferably be limited to localized dermatoses. In certain generalized skin affections it may be of service in treating regions particularly affected. Finally, it should not be applied to the face nor in patients who cannot give up their occupations while under treatment, as it is liable to give rise, of itself, to intense erythema. He employs the following formula:

Coal tar	6	o	ʒiss
Alcohol (95 per cent.)	4	o	ʒj
Ether	2	o	gtts xxx

Apply locally by means of a camel's-hair brush. The tar may be easily removed by rubbing with olive oil.

STATIC ELECTRICITY IN VARICOSE CRURAL ULCERS.

Dr. L. Marquant (*Wiener Medizinische Presse*, No. 43, 1894), in a recent dissertation from the Lille Medical School, reports good results from the use of static electricity in the treatment of varicose crural ulcers. The ulcer is first washed with a weak solution of carbolic acid or sublimate and then covered with a thin layer of cotton. The patient is placed upon the isolating platform and connected with the negative pole of the static machine. The other pole is brought near to the ulcer, yet not so near as to produce sparks nor so distant as to give rise to the "electric wind." After the current has acted for ten minutes, the leg is dressed with a simple antiseptic dressing. This is renewed twice a week, while the electric sittings are given three times a week, so that once in the week the current acts through a dressing of three layers. The cases treated thus he divides into three groups. In the first he places those where the ulcer is the only symptom. In all of these cases the improvement was rapid and began almost immediately after commencing treatment, in that the itching and pain disappeared. The œdema and redness of the surrounding soft parts gradually decreased, the varicose dilatations disappeared and the ulcer cicatrized. In the second series of cases there was, besides the ulcer, a debilitating factor, as advanced age or a chronic disease. In these cases the improvement appeared late and after amelioration of the general condition. In those cases where the static current led to no improvement, all other means also failed.

EXTRACT OF THYROID GLANDS IN EXOPHTHALMIC GOITRE.

Dr. Jules Voisen (*La France Medicale*, No. 43, 1894) recently reported before the Hospital Society of Paris the case of a woman affected with Basedow's disease who received six to eight grams of extract of sheep's thyroids, to be taken in two doses daily, before each meal, in a little sauce. In fifteen days a notable improvement was noticed. The excessive irritability, trembling, insomnia and palpitation of the heart with a sense of suffocation were greatly improved, while the œdema

* In charge of the translator, F. H. Pritchard, A.M., M.D.

of the lower limbs had disappeared and her pulse rate had fallen to 100.

ETHER AS AN ANESTHETIC.

Prof. H. Fritsch (*Medicinische Neuigkeiten*, No. 39, 1894) would see ether occupy the place of chloroform in gynecological and obstetric practice. He believes the outlook better for anemic individuals in long-lasting operations with ether. In obstetrics, in forceps operations, version, Cæsarean section and whenever there is danger threatening the child, it is always to be preferred.

SULPHUR IN DIPHTHERIA.

Dr. A Forslund (*Revue Internationale de Medecin et de Chirurgie Pratiques*, No. 17, 1894), of Stockholm, claims that insufflations of sulphur are capable of destroying the toxines of diphtheria while they are limited to the pharynx and tonsils, thus preventing their entering the system and giving rise to general symptoms. The sulphur, he says, is insufflated until the false membranes are completely covered with the powder. It is allowed to remain there for from twenty to thirty minutes, after which it is irrigated off by water which has been boiled and allowed to cool. This local treatment is repeated two or three times a day, according to the requirements of the case. He believes it a specific in ulcers which are greenish, with a tinge of black and of a disagreeable odor—gangrenous variety. The burning pains are also quieted by the remedy. He rejects the mercurials and all methods whereby the mucous membrane is caused to bleed. A solution of the bicarbonate of soda (15 : 300) may be used as a gargle. Seventy-six cases have been cured by this method.

TREATMENT OF SMALL-POX BY EXCLUSION OF THE RED RAYS OF DAYLIGHT.

Dr. Henry Benckert (*Hygeia*, liv, 7, pp. 11–22, 1894) has treated seventeen cases of small-pox by exclusion of the red rays of daylight, a method which has been brought forward by Finsen, a Danish physician, and tried by a number of other observers, chiefly Scandinavians; of these seventeen cases five were varioloid. As a rule the secondary fever was not observed owing to the exclusion of the irritating chemical (red) rays of light. In one case there were a few very small cicatrices on the end of the nose and in another on the fingers. Desiccation set in more rapidly and the crusts detached earlier than usual. The varioloid forms were influenced a little, but to a less extent. The results of his experience would suggest its trial.

SAFE CHLOROFORM ANESTHESIA.

Drs. Langlois and Maurange (*Muenchener Medicinische Wochenschrift*, No. 43, 1894) have sought to obtain a variety of mixed anesthesia which would prevent cessation of the heart's action, the greatest danger of chloroform anesthesia. Physiological experiments have demonstrated sparteine to possess two marked actions, a strengthening influence upon the heart and an inhibitory one upon the pneumogastric. Clinically, their method is as follows: A half-hour before anesthetizing, one c.cm. of the following mixture is injected hypodermically:

Morphine muriate....	0	1	grs. jss
Sparteine sulphate	0	3–0.5	grs. ivss vijss
Distilled water, ad.....	10	0	ʒ ijss

One c.cm. of this solution will contain 0.01 of morphine and 0.03 of sparteine. In 148 operations with chloroform as an anesthetic and employment of this preparation, no disturbance of the heart was remarked, whatever the disease, the duration of the operation, the age of the patient or his previous disease—tuberculosis, hemorrhage, albuminuria, convalescence from typhoid fever, etc. In all cases anesthesia rapidly followed, but little chloroform was necessary and the pulse was full and regular during the entire operation. In a few cases where an operation of two hours and over was necessary, the respiration became somewhat feeble, yet the heart continued to beat with full force. In these cases rhythmic tractions of the tongue permitted a continuance of the operation.

THYROID FEEDING IN MYXŒDEMA.

Dr. J. J. Schmidt (*Deutsche Medicinische Wochenschrift*, No. 42, 1894) has obtained good results with thyroid feeding in a desperate case of myxœdema. He advises beginning with small doses, smaller than those usually given, until the cutaneous swelling begins to disappear. About one gram (grs. xv) a day will suffice and not expose the patient to danger, and may

be ordered instead of the usual tablet once a week. One of White's tablets may be also given daily, later two to three, for four or five weeks, with the same results as with feeding the fresh extract. With appearance of alarming symptoms, headache, vomiting and pain in the kidneys and increasing pulse rate, all forms of the extract should be discontinued at once. He regards a long-lasting treatment with careful watching of the patient as requisite for a definite cure.

PUERPERAL INTERMITTENT FEVER.

Dr. Solowieff (*Revista de Ciencias Medicas de Barcelona*, No. 18, 1894), from three cases of this rare complication of childbed and a study of the literature, concludes as follows:

1. Intermittent fever during pregnancy and childbed is a rare disease.
2. Diagnosis and treatment are necessary, as it may influence the mother and fœtus, causing either abortion or death of the fœtus.
3. In childbed it may prevent the secretion of milk and the involution of the uterus.
4. It is to be distinguished from other febrile affections of the puerperium, and especially puerperal septicemia.
5. The treatment is the same as in the non-pregnant, yet it is useful to combine quinine with opiates.
6. In nursing women with intermittent fever the tannate of quinine is indicated; opium, if used, will dry up the secretion of milk.
7. In asthenic parturient women small doses of arsenic are of service.

CORYL, A NEW LOCAL ANESTHETIC.

Dr. Gaubert (*Hospitals-Tidende*, No. 34, 1894), of Paris, has invented a new local anesthetic by mixing certain proportions of ethyl and methyl chloride. It is stated to act better than ethyl chloride, which in the mouth does not give as good results as in other portions of the body and in the molar teeth of the lower jaw, where its action is only to be obtained in two to three minutes, during which time it would be impossible to keep the saliva away from the gum, so that its action would be a failure. Methyl chloride acts much more rapidly than the ethyl compound; its boiling-point lies 22° below zero, while that of ethyl chloride is 10° above. Alone the methyl preparation has such a powerful freezing action as to cause necrosis of the tissues. Coryl is a mixture of the two with a boiling-point at zero; it is a colorless liquid of an ether-like odor and not easily inflammable. It is put up in steel tubes under a pressure of three atmospheres. Its action lasts from fifteen to twenty seconds.

TREATMENT OF FRECKLES AND CHLOASMA.

In the *Wiener Medizinische Presse*, No. 43, 1894, the following formulæ are advised in freckles:

Corrosive sublimate.....	0.25-1	o	grs. iv-xv
Colorless extr. hamamelis, Glycerine, Alcohol....	āā 50	o	ʒjss

To be applied locally morning and evening.

Less irritating is the following:

Muriate cocaine.....	1	o	grs. xv
Boric acid.....	15	o	ʒiv
Rectified alcohol.....	200	o	ʒvj ʒij

To be applied locally on compresses.

In chloasma the following is spoken highly of:

Corrosive sublimate.....	o	60	grs. ix
Muriate ammonia.....	4	o	ʒj
Rectified alcohol.....	50	o	ʒjss
Colorless extr. hamamelis	100	o	ʒij ʒj

To be applied locally on compresses.

All of these remedies are to be discontinued at once as soon as a pronounced irritation of the skin follows; this is best treated by an oxide of zinc salve. As soon as these symptoms of irritation disappear treatment may be begun again.

DANGERS OF BETA NAPHTHOL SALVE.

Dr. Baatz (*La Sémaine Médicale*, No. 59, 1894) warns against a possible danger in prescribing inunctions of a salve of beta naphthol. He treated two young children, of six and eight years respectively, with a salve of beta naphthol locally for the itch (two per cent.). The little patients were cured of their itch, but three weeks later they were seized with œdema of the lower limbs and albuminuria; one of the children died. The diagnosis was confirmed by the necropsy. None of these children had had symptoms of this disease before.

CORRESPONDENCE.

REPORT OF PARASITIC ENTOZOA ENCOUNTERED IN GENERAL PRACTICE IN TEXAS DURING OVER FORTY YEARS.

EDITOR MEDICAL AND SURGICAL REPORTER: Dr. F. Herff (*Texas Med. Journ.*, ix, 1894, pp. 613–616) give some interesting and important statistics of paraitess which he has found in San Antonio.

1. *Tænia saginata* (*mediocanellata*) is extremely common, so that in some localities it is found in nearly every family. He has never found the cysticercal stage "in beef or veal or yet in man." [The cysticercal stage does not occur in man.]

2. *T. solium.* Also very common, especially in German settlements. "The cysticereus is very often met in the pork. I will remark that I have frequently met with living and moving scolices of tænia in well-water, and am confident that they were introduced into wells by contamination from privies or by carelessly cleaning chamber-vessels near the well. Wherever such scolices were found one or several members of the family had tænia, which in some instances was discovered in consequence of the finding of the scolices in the well." [What can it be that the author has found in wells? I am entirely at a loss to know.]

3. *Bothriocephalus latus* found twelve times, generally among Poles and Swiss; two cases in persons from the other side of the Rio Grande. [This find, if correctly determined, is very important.]

4. *T. echinococcus.* Herff states that he has found this parasite in every dog he has examined; that it is common in the muscles and liver of the jack-rabbit; not uncommon in the human body (has found it six times, one case in the eye).

In *T. echinococcus* the author has evidently included a number of species. The forms in the rabbit are evidently *Cysticercus pisiformis* and *Cœnurus serialis*, both of which have several times been sent to me from Texas for determination. It is erroneous to state that *T. echinococcus* is so common in the dogs of Texas! Herff probably has *Dipylidium caninum* and *T. serialis* before him. If this species were as common as Herff reports, we should expect to find the larval stage in nearly every man, cow, horse, hog and sheep in Texas. I have already stated in another publication that *not one* of the twenty or twenty-five supposed cases of hydatids from Texan cattle which have been sent to me for determination were Echinococcus hydatids.

The cases recorded in man by Dr. Herff seem to be genuine.

5. *Trichina spiralis*, reported in eighteen persons, no deaths.

6. *Ascaris lumbricoides* frequent, especially among negroes.

7. *Trichocephalus dispar* not found.

8. *Anchylostoma duodenale*, once at least; several other cases suspected.

9 and 10. He also believes he has met with cases of *Bilharzia hæmatobium* and *Filaria sanguinis hominis*, but the data he brings forward are not convincing.

From this paper we see that a physician can gather very valuable data in his practice, but that more care is necessary in determining the parasites. In case a person is in doubt as to the form he has before him, he should send it to a specialist for determination. I shall be only too glad to determine forms forwarded to the National Veterinary College, the United States National Museum, the Department of Agriculture or Georgetown Medical College.

Washington, D.C.

Salicylic Acid.

Salicylic acid and its compounds may be found useful in scanty and delayed menstruation. They should not be administered to pregnant women who have a predisposition to abort or who suffer from menorrhagia and metrorrhagia. Their administration should be watched carefully in all cases of pregnancy, and on the appearance of any "show" or anything resembling labor pains, should be discontinued.

HAROLD H. KYNETT, A.M., M.D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, NOVEMBER 17, 1894.

EDITORIAL.

THE A. A. R. S.

These times in which we live, among other things are remarkable for the multiplication and organization of new medical societies and new medical colleges.

The motives which inspire founders are sometimes commendable, but it is to be feared that in not a few instances the ulterior purpose in view in their creation is not so much for advancing the legitimate aims of medical science as for self-advertisement and aggrandizement.

We have a pertinent illustration in the birth of a new society with the high-sounding title of "The American Academy of Railway Surgeons."

The general trend of modern medicine is to spread itself into innumerable specialties. One of our large hospitals in Pennsylvania has recently established a special ward for appendicitis cases. This would imply that the next claimant for honors in a new field will be the "Appendicologist."

When the National Association of Railway Surgeons was first organized, many objections were made to it on the score that it was not needed and that it would be manipulated in the interests of the railroads to the detriment of the profession and the public alike. In this, however, we have been mistaken.

There is only one "national" surgical association in this country, and this is so local and limited in membership as not to fairly represent, either in numbers or talent, American surgery. For it is well known that some States have no representation in it at all, and, moreover, many of the most eminent and distinguished members of the craft have been denied membership therein. For these the National Association of Railway Surgeons offered the opportunities heretofore denied them.

It is now well known, too, that this organization is in no respect the tool of the railroad companies. As a matter of fact, many members pay their own fares to the annual convention, and others are allowed only such rebate as is extended by the railroad companies to any national convention.

But why another association of railroad surgeons—Academy, so called? The editor of the Columbus *Medical Journal*, who

was the honored and trusted treasurer of the elder body, says in the issue of that journal for October 16th, that it is "the outgrowth of a scandalous row at the Galveston meeting," etc. But while stigmatizing an organization which had placed unbounded confidence in him, and even at the Galveston meeting had selected him for its editor, why not state all the facts in order that the A. A. R. S. may be better understood, and the whole profession be better informed on the new subject of railway surgery?

Is it the fact that the new journal of the National Association was forced on its membership by its then editor; that he invited prominent members of the profession to join the editorial staff; that after the Galveston meeting he at once set to work to destroy the journal which he, but a few short months before, had forced on the association, by directly corresponding with these gentlemen and requesting them to withdraw?

So far as we can learn, the only scandal committed at the Galveston meeting was that the candidates presented by the Committee on Nominations were not accepted by the organization, and the meeting substituted a set of candidates selected from the floor; a course which the presiding officer, Dr. Galbraith, declared regular.

It looks questionable when, not satisfied with trying to destroy the journal, the only salaried officer of the organization proceeds to further undermine the National Association, and actually proposes to form a new society out of the body of the parent before the corpse is cold.

So soon as the Executive Committee were informed of the true state of affairs, it promptly convened in Chicago, removed Dr. Reed from the editorship and appointed Dr. Wm. B. Outten, of St. Louis, to succeed him.

We are not interested with side issues which specially concern but few. But when a new "academy" of a national character is to be created, it is just and proper that the whole profession should be made acquainted with its objects and the purposes it proposes to fulfill.

A SIDE-LIGHT ON THE "AUTOCRAT"—AN AUTOGRAPH LETTER FROM DR. HOLMES.

A friend whose fame is unsurpassed by any name in the American profession, but whose modesty is greater even than his fame, allows THE REPORTER to present its readers the following interesting letter from the "Autocrat:"

BOSTON, October 23, 1874.

MY DEAR SIR: I happen to be suffering from influenza to-day, with so much lassitude and febrile disturbance that I do not feel able to answer you as I should be glad to. But I am unwilling to wait longer, and therefore I must now thank you most cordially for the letter and the pamphlet which came soon after it. The testimony you bear to the sad fact which I laid before the public so many years ago confirms, if confirmation were needed, the thesis I maintained.

It is *thirty-one* years since (April, 1843), in the *New England Quarterly Journal of Medicine and Surgery*—a periodical of merit, but which died with its fourth number—I published an article which I considered settled the point of the communicability of puerperal fever from one patient to another by the accoucheur.

Dr. Meigs and Dr. Hodge attacked my position in a way which made me ashamed, both talking like class declaimers in the face of facts which people of common sense could only interpret in one way. I confess that *I* declaimed too, but I only fired powder after firing shot and shell. I have been sick of the name of "Professor" ever since.

Hundreds of lives might have been saved if, instead of ranting to their ignorant classes, they had enforced the disagreeable truth I had made plain enough for those who would not shut their eyes.

Twelve years later, in 1855, I reprinted the essay with additions, and reprinted it once more in my volume, "Currents and Counter-Currents," printed in 1861.

Of course, being separated as I have been from medical practice, I still could not help being interested in Dr. Barker's book, which he kindly sent me, and I assure you that I feel very much obliged to you for sending me your notice of it, to say nothing of the fact that I read a good part of your address, which seemed to me eminently readable as well as of great practical significance.

Forgive the petulant way in which I have spoken of the two distinguished gentlemen, one of whom was very probably your teacher. You may set it down partly to the erethysm which sometimes accompanies these wretched influenzas.

Believe me, dear sir, very truly yours,

O. W. Holmes.

ABSTRACTS.

THE DRUNKARD AND HIS CURES.

W. W. POTTER, M.D., Spokane.

I shall deal with this subject in a general way only, and yet my hope is that some practical points may be developed.

Webster defines the "drunkard" to be "one who habitually drinks to excess." Billings defines "drunkenness" as a "temporary mental and physical disorder from the ingestion of alcohol." As drunkenness is produced by many drugs, such as opium, cocaine, chloral, etc., the above definitions are incomplete and should be changed so as to include everything which intoxicates. For there are many kinds of drunkards and many degrees of drunkenness. The primal cause of confirmed drunkenness, or inebriety, as some prefer to call it, is the formation of a habit. The habit grows slowly or rapidly, according to the will and environment of the individual, and may be formed wittingly or unwittingly. Diseased appetites and organs are the result of habit. The habit itself is distinct from and always precedes the diseased condition. Moral perversion or blindness is the foundation of the habit, and diseased conditions are but symptoms indicating degrees of it. These conditions may be remedied with medicine — but medicine alone will not cure the habit. Hereditary taint does not develop habit— it does develop, however, the capacity to rapidly form one. Heredity bequeathes only aptitude, not appetite, and it is fortunate indeed that that is all it does entail.

Many excellent physicians have of late years stoutly maintained that the habit of drunkenness was simply a disease, classing it among the neuroses, and the charlatan has worked out their theory to his financial advantage and many a patient's ruin.

When, by the aid of medicines, a habit is broken, this is called a "cure." But the great majority of such cured ones relapse, the time of relapsing depending on the intoxicant formerly used and the temperament, physical condition and environment of the subject. Cure and relapse follow cure and relapse with ever-increasing frequency when medicine alone is relied upon to effect a cure.

The preacher declares that this habit is a sin, seldom recognizes diseased conditions, and very rarely does he rightly estimate the value of medicines as aids. He seeks to apply his gospel remedy only, and he, too, meets with many sad failures, for he does not realize the "weakness of the flesh."

Both doctors and preachers are right in their views, yet not wholly so, for the exact truth is found between the two. The doctor has studied only results; the preacher has seen only the cause. The doctor prescribes for physical and moral effects; the preacher for moral and spiritual. The doctor treats symptomatically, the preacher radically. If we combine the views of both physician and preacher we have a complete diagnosis. Combine their remedies and we have a complete

cure; for on the moral field the main battle with this bad habit is always fought; on the medical field sharp, but only preliminary skirmishes.

This much concerning the drunkard himself; now let us consider some of his cures.

You have all prescribed for this habit. You have tried cinchona, rubra, the bromides, the different salts and combinations of gold, strychnia by mouth and hypodermatically, and many others. With the aid of these and tact in withdrawing the intoxicant, you have found, as I have, that it was comparatively easy for the drunkard to break his habit, but exceptionally so for him to hold it thus. Though his chain of habit was broken, the links were left and still oppressed him. You saw something of his difficulties while breaking this chain. Did you appreciate his easy task in mending it again? This point is rarely recognized and guarded against except by those who have had personal experience. The moral treatment is either wholly neglected or but feeble in effort. Yet even this is better than false teachings.

The mythical bichloride of gold has perhaps been a subject of your investigation. You have analyzed it. Found only well-known drugs, and but a trace, if any at all, of gold, yet some former patient of yours has perhaps taken this treatment and is to-day an evidence of some mysterious power, for now he is a sober, industrious man. Did you study the method of giving, as well as the medicines given? Did you note the moral treatment as well as the physical? Had you done this you would have discovered that the moral effect of the teachings, the surroundings, and the methods fully accounted for the results. To illustrate this point, I quote the following from an article of Dr. C. F. Chapman, in the *Medical Recorder* of February, 1893. He says:

"Being determined to find out something definite about the matter, early last spring I obtained a position as physician to a gold-cure sanitarium. As I have had personal experience in treating about 300 cases, I feel that the few remarks I can make may be of interest to you. And, first, I am prepared to give you the formulary of the gold treatment, which is almost, if not quite, the same in all these institutions, as follows:

"No. 1. Tonic, known as the 'dope.'

Aurii et sodii chlorid	gr. xij
Strych. nit	gr. j
Atropiæ sulph	gr. ¼
Ammonii muriat	gr. vj
Aloin	gr. j
Hydrastin	gr. ij
Glycerinæ	ʒ j
F. E. cinch. co	ʒ iij
F. E. coca erythrox, Aquæ	āā ʒ j

M. Sig.: ʒ j every two hours.

"No. 2. Injection, known as the 'shot.'

Strychniæ nit	grs. 9.1
Aq. dest	ʒ iv
Potas permangan	q.s. to color

M. Sig: Begin with five drops, which equals 1-40 of a grain of strychnine, and increase one drop at each injection until the physiological effect is produced. Four hypodermic injections to be given daily at 8 A.M., 12 M., 4 and 8 P.M.

"No. 3. Used with No. 2.

Aurii et sodii chlorid	gr iiss
Aq. dest	ʒ j

M. Sig.: Three drops every four hours in combination with the strychnine solution for the first four days.

"This last prescription is used only for the moral effect, which is produced in the following manner: Five drops of the strychnine solution are drawn into the syringe, then three drops of the gold solution are drawn in and mixed. This produces a golden yellow color, to which attention is called, and the patient is further assured as to the reality of the presence of the gold by the stain left on the skin after the hypodermic needle has been removed. A positive disgust is, in almost if not in every instance, produced in the following manner: The patient is given a drink of whisky, then the so-called bichloride of gold solution (really a solution of strychnine) is injected in his arm, but at the same time, and without his knowledge, he receives one-tenth of a grain of apomorphine. It takes but a comparatively short time for the emetic to produce its effect. Now the patient acknowledges the wonderful power of the hypothetical gold compound and surrenders unconditionally. From an unbelieving scoffer, he is changed into a disciple and supporter of the prophet."

Dr. Brownson, who investigated this treatment independently of Dr. Chapman, gives a formulary for the "dope" and "shot" essentially the same. He then says:

"They are told that they can have all the liquor they want. If the patient asks for a drink of whisky he gets it, but instead of the injection of strych. nit. he receives one of apomorphine, one-tenth of a grain; of course the whisky makes him

sick. He is unable to retain his once-favorite beverage, and he writes his friends glowing accounts of the great change and new life that have come over him since taking this wonderful cure, which, he feels sure, could only have been brought about, as Mr. Keeley himself said in a lecture here recently, by Divine appointment."

On the main point both observers are agreed. It is the method, not the means, that has apparently accomplished wonders. But my observation has been that such cures seldom last more than six months; of course there are exceptional cases of longer standing. These patients are taught and believe that they are radically cured, and safe to go into temptation; but sooner or later they find, by a bitter relapse at an unguarded moment, that they have been deceived. Is it not easy to travel over a difficult road with congenial companions, especially so if all are keeping step to the same music? And is it not difficult to make that same journey entirely alone? But the country is now full of relapsed "graduates," and these are the proofs of the falsity of the disease theory. The people are seeing the actual results for themselves, and holders of institute stocks of all kinds are finding themselves duped.

I here note Dr. Breed's article on "Treatment of Alcoholism by Strychnine Nitrate Hypodermically." He holds contrary views to those just expressed, and his detailed cases show what this drug will do unaided. I agree with the doctor in extolling the virtues of this remedy, and am heartily in accord with his conclusion that "there is no reason why the public, which places its life in our hands daily, should be obliged to offer up sacrifices upon the shrine of quackery, when men can be treated privately, safely and efficiently by any family physician and thus avoid publicity, danger and expense."

There is another kind of remedy on the market. This plan is by gradual reduction, taking from two to six months for a cure. This has, at least, the merit of not being composed of dangerous ingredients. The moral effect is secured in the usual style of the charlatan.

A third class contains only substitutes equally enslaving, and though the patient is freed from his original intoxicant, he is a slave to his antidote. We can only condemn such men and such methods. Yet from these three kinds of cure we can learn a valuable lesson. They all give minute attention to the patient and carefully prescribe in detail.

A fourth method, now almost if not quite obsolete, consists in producing physical revulsion by saturating foods and drinks with the accustomed stimulant. This has proven a failure. I think we can see the reason why in a statement of one of its strongest advocates. In the introductory of Dr. F. H. Hubbard's book, entitled "The Opium Habit and Alcoholism," he states: "We shall not refer to the moral aspect of our subject." Is not this the very place where the revulsive should have been applied? Did not the trouble begin here?

Mention must be made of a purely moral agency, which is reported by recent writers as very efficacious. I refer to hypnotic suggestion.

Forel (*Wood's Medical and Surgical Monograph*, vol. v, No. 1) reports a cure of an incorrigible drunkard 70 years of age. The cure had lasted two years or up to the time of writing. The patient was, however, living with the doctor all this time, which leads one to ask the question, Would the same result have been otherwise obtained? Forel also recommends this method for "bad habits" of all kinds.

Kingsbury (*Wood's Medical and Surgical Monograph*, vol. xii, No. 2) reports a cure of nine months' standing; hypnotism was still being used at intervals, however. He reports two other cases, one of which is remarkable from the fact that though the patient had been a user of stimulants to excess for ten years, yet "after the first sitting all appetite for alcohol vanished." Unfortunately the record stops with this statement. He also details two cures of other moral perversions.

In the *Medical News* of March 31, 1894, we find an interesting article by Assistant Surgeon Bushnell, of the United States Army, on the use of hypnotism in chronic alcoholism, and while this means alone in his hands has apparently accomplished all that is done by any other plan, yet his detailed cases tell the same old story of relapses. Yet I believe that this is a means that will soon be used extensively as a valuable aid in curing drunkenness.

Dentists of repute, like Dr. Fillebrowne,

of Boston, and others, are performing dental work painlessly by it (*Dental Cosmos*, September, 1893, p. 985), and no less distinguished a surgeon than Professor Senn, of Chicago, is reported as using it for anæsthetic effects, and successfully. This evidently powerful, though but little understood, moral remedy should be thoroughly investigated. All prejudices must be laid aside, and, if proven efficacious, the victims of drink and drug should be given the benefit of its aid. We stand on the broad platform of true eclecticism and we cannot refuse to use the good wherever we find it.

Therefore, I here mention another cure. 'Tis religious conviction; and I know of no more powerful and lasting moral revulsive than this one. Cures of this kind we have all witnessed, and I am compelled to state, after three and one-half years of honest seeking for the best remedy, that this is the only one that has any holding power in it. In other words, provides against a relapse. Relapse is the rule with other remedies, but not so with this one, and majorities prove the preacher's theory correct. This remedy is as unpopular today as ever, but it is as powerful as when Naaman tried it. As physicians we can, of course, understand that the *vis medicatrix naturæ* works out the physical cure in these cases, and those treated by hypnotism as well; but, after all, this is the main agency, whether recognized or not, that is most powerful in all cures.

After my short experience with this class of patients, I am of the opinion that drunkenness is curable if the drunkard wills to be cured. But we must be sure he wants to quit, to the extent that he is willing to be guided by us for a long time after he has quit. Remember he is but a weak child when this habit is first broken, and needs child-like protection and guidance. Here is where both physician and patient ofttimes err, especialy if the patient appears to be physically strong. He must now be kept busily occupied at some healthful employment, and should be taught that he must be perpetually on guard against the next dose.

While secret remedies have no advantage whatever over non-secret medicines, the secret use of them with the patient is absolutely necessary, and careful, prompt attention to all details inspires his confidence and insures success.

Whatever we do, we must be careful that our moral influence is in the right direction; ever remembering that a medical cure is but a half cure; that we are dealing with a compound ailment—sin and sickness—and our remedies, though grand aids, are at best only palliatives. Never bar the way of the preacher by teaching that this habit is only a disease. The disease theory is popular with those who find difficulties in the way of breaking their habit, but it is also an excuse for others to continue their debauches and deviltry. The preacher's remedy is needed always to complete the cure. We must teach these patients to be ever on guard against the drink and drug storms that are yet to come; we must show them then the place of sure protection when they do come, and instruct them how to form new habits to replace the old; for as

> "Thread by thread the strand we twist
> Till they bind us neck and wrist," so
> "Thread by thread the patient hand
> Must untwine, ere free we stand."
>
> "First across the gulf we cast
> Kite-borne threads, till lines are passed,
> And habit builds the bridge at last."
>

Double Femoral Herniotomy.

Dr. S. E. Milliken, New York (*La Revista Med.-Chirurg.*), reports a case of double femoral herniotomy in a woman at the advanced age of 64 years. Deep sutures of kangaroo tendon were used to close the crural canal, while catgut was employed for bringing together the skin wounds. The dressings were changed for the first time on the tenth day, when union was found complete and the superficial sutures had been absorbed. The highest elevation of temperature was 101° F., which occurred within forty-eight hours and was attributed to the shock of the operation. Conclusions:

1. Age is no contraindication to the employment of the radical cure of hernia.

2. Asepsis and antisepsis should be carefully observed.

3. Even in cases of strangulation, the radical cure should be attempted if the condition of the patients warrants the delay.

4. When the truss becomes a source of annoyance, or if the hernia is difficult to retain, the operation should be performed without delay and before the strangulation occurs.

SUNSHINE AND MICROBES.

One of the most novel and extremely interesting revelations concerning the sun's terrestrial influence has been recently made in connection with the life of microorganisms. As every one knows, microbes, while capable of performing the most indispensable service to man in such important directions as the breaking up of refuse organic matter, the fertilization of the soil, the production of alcohol, etc., may and do become extremely objectionable when they venture outside their particular spheres of utility. Under favorable conditions a new generation of bacteria may be inaugurated every twenty minutes or half-hour. Thus it can be calculated that if such multiplication went on without let or hindrance, a single bacillus would in the course of twenty-four hours have given rise to a progeny four times as numerous as the whole population of London, while at the end of forty-eight hours their number would be represented by the wholly unmanageable figures—280,000,000,000,000! One agency which has only recently begun to be understood and appreciated is the power of sunshine to destroy these microorganisms.

The first and most important step in revealing the cleansing and disinfecting properties of sunshine was made in this country about sixteen years ago by two Englishmen of the names of Downes and Blunt. These investigators established the remarkable fact that if certain liquids capable of undergoing putrefaction, or in common parlance of "going bad," were exposed to the direct rays of the sun, they remained perfectly sweet, while exactly similar liquids kept in the dark became tainted and exhibited innumerable bacteria under the microscope. Numerous most important and interesting experiments were made by these investigators, with the object of finding out how these wonderful results were brought about and upon what factors they were dependent. In the first place, it was ascertained that the oxygen of the air had a marked effect in assisting the sun's work, and that the bacteria suffered more from the sun's rays if the proportion of oxygen was increased, and less if it was diminished, thus clearly pointing to processes of oxidation as being the cause of the phenomenon. Recently M. Momont, in the Institut Pasteur, has obtained more exact information confirming these experiments by exposing the bacilli of anthrax to sunshine in the presence and absence of air, with the result that while the anthrax bacilli exposed to the sun in the presence of air were killed in two and a half hours, similar bacilli placed in a vacuum were still alive after fifty hours' exposure to sunshine.

The next problem to be attacked was to ascertain whether all the solar rays were equally responsible for this important result or whether the different-colored rays composing the sun's beams produced different effects, as is known to be the case in those important vital processes which go on in green plants. Many investigators besides Downes and Blunt have bestowed attention upon this interesting question, but it was perhaps first most successfully attacked by Dr. Geisler, of St. Petersburg, now some two years ago. This investigator decomposed the white sunbeams by means of the prism, and then exposed typhoid bacilli to the light of the spectrum. The rays at the red end he found had little or no effect at all on the growth of the bacilli, while the most powerfully deleterious action was obtained in the ultraviolet, the effect becoming less and less marked in passing from this to the red. On this point, in fact, all investigators are agreed—that the rays which exert this destructive or inhibiting effect on bacterial life are precisely those which also exert the most powerful action on the ordinary photographic plate.

Even if the exposure to the solar rays is not sufficient to actually destroy the bacteria, it may yet profoundly modify their character and bring about the most important changes in their subsequent behavior. Dr. Palermo, of Naples, placed some of Koch's cholera bacilli in the sunshine for various periods of time, and he found that while, when he protected them from the sun, they killed guinea-pigs in eighteen hours as usual, after they had been "sunned" for from three and a half to four and a half hours they were perfectly harmless, and the animals experienced no evil results whatever from being treated with them. The cholera bacilli

which refused to kill the guinea-pigs had not been destroyed, nor had their total number suffered any diminution by the action of the sunshine during this short time, but their inability to work mischief was directly due to the removal during this exposure of their virulence or disease-producing powers. More than this, the further important discovery was made that those guinea-pigs which had survived the above inoculation with these sunshine-exposed or insolated cholera bacilli, had acquired immunity toward this disease, or, in other words, were protected from contracting it afterward, much in the same way as vaccination with cow-pox protects the individual from an attack of small-pox. Thus when eight days later these particular guinea-pigs were inoculated with virulent cholera bacilli they were quite unaffected by doses which to ordinary guinea-pigs proved rapidly fatal. Thus by exposure to sunshine these disease microbes were not only deprived of their sting, so to speak, but were converted into useful servants in protecting their former victims from the attacks of their still viciously disposed brethren.—*Nineteenth Century.*

THE CURATIVE SERUM IN DIPHTHERIA.

The meeting of the "Naturforscher" could not possibly pass without a declaration on this all-important subject, and for this Behring and Ehrlich were the heroes. Behring led off with the first paper. He said the curing of acute disease by means of specific applications was not thought of till very recently, when the toxines were found to possess an antidote for tetanus and diphtheria which are not exactly complete in all the details yet, although far advanced in proving the efficacy of the method now adopted. Diphtheria and tetanus appear to be solved, and shortly typhoid, pneumonia sysa, if not tuberculosis, may be added to the list. He tells us that his attention was attracted to the subject in 1880, when wounds and bacteria were receiving special attention. In pursuing this further, he experimented with iodoform in this direction in the following year. From these experiments he concluded that the bacteria themselves were not to be wholly considered, but that the toxines or products were more important than the microbe itself. In 1890 his first success was in the cases of diphtheria in guinea-pigs, which has now been extended to man. This anti-toxic immunity was then proved to reside in the serum; but Ehrlich, by more extensive experiments, has proved its existence in plant life also. It is found by experiment that the oftener the inoculation the greater will be the immunity; the protective power remaining the same in quality, but the quantity varying in different animals. Another step forward was made by Pasteur in his weak and virulent cultures where immunity was obtained by a slow process of growth. This method may now be relegated to the past as a mark of our forward progress and success in the serum treatment for diphtheria and tetanus, which may be extended indefinitely. We have material before us that may open up a great future in the records of therapeutics. We have now almost mastered the proof of applying an antidote for infectious diseases on the first appearance of the disease or checking and modifying the chronic. Protection is equally established, but whether the microbe is killed or the receptive faculty of the body destroyed is not yet clearly demonstrated.

With this knowledge of diphtheria we are now able to calculate our gain on the effects it will have on population during the next decennium if the serum therapeutics be adopted. In Germany and Austria alone, roughly speaking, 2,000,000 children die every ten years from diphtheria. Of these it is assumed under the new *régime* that one and a half millions will be alive at the end of this period. It has now been admitted that within the first three days 10 per cent. of the cases die, and 5 per cent. of those commenced within four hours. If the prophylactic virtue of the serum were commended sufficiently early, this moiety of death could be averted, which can be accomplished with very small doses at half a mark each.

Ehrlich said that we owed a deep debt of gratitude to Behring for his untiring efforts on this subject without remuneration or assistance of any kind. After all the albuminous fluids of the body had

been tried, the blood serum had at last been found to be the most practicable. The milk of an immune animal can also be used with efficacy, but cannot always be practicable. The Berlin "Kinderanstalten" have not been so successful in the use of the serum as many other institutions appear to have been, as 53 deaths are recorded out of 530 attacks. These results must be taken with reserve, as too small doses were given at the commencement of the treatment, as proved by the better results later on. He refrained from foreign statistics, and promised to keep to his own results. Of 40 cases, 20 of whom were tracheotomy ones, only 6 of the latter class died. In other 41 cases where the serum was not used 18 died. On another occasion he treated 48 cases and only 6 died, making a death-rate of 15.05 per cent. of the total number treated. If the moribund cases on reception were eliminated this number would fall to 8 per cent., or if those suffering from nephritis, myocarditis, etc., were removed, the genuine diphtheritic mortality would be under 3 per cent.

Referring to the clinical aspect of the drug, a critical fall of temperature was noticeable on the first dose being applied in fresh cases; the pulse was similarly affected, after which the euphora set in. The prognosis is always favorable in early cases, although advanced ones must be received with caution.

The usual advertisement followed that it was manufactured by Meister Lucius, under the superintendence of himself and Aronsohn; that there were three sizes in the market, viz., 600, 1,000 and 1,600 c.c. tubes, the dose being 10 c.c. For freshness he recommends the 600 tube, containing ten doses and costing five or six marks.

In the discussion that followed these papers, Aronsohn gave a description of the preparation of the serum. His method was to obtain the most virulent form, so that the antitoxin would be found in the most concentrated form. His opinion is that the curative effects of the serum are not obtained unless the culture be virulent. He claims to be the first who made use of the horse. To increase the virulence, he used to drive air and nitrogen over the cultures, but is now in favor of the growth method, by which the culture assumes a thick white lamella so virulent that one dose, 0.5 in strength, will kill a guinea-pig in forty-eight hours.

INDIVIDUAL DISPOSITION.

Wasserman raised the question of resistance in the blood of the aged; the older a person was the organism was correspondingly resistant, and between 50 and 60 diphtheria could not be induced. In the laboratory he had taken 1 c.c. of blood from such an individual and found it perfectly antitoxic, having ten times the strength of one that will kill a diphtheritic culture. The blood can be accurately estimated according to age. In ten children varying from 4 to 15 he found antitoxic virtue in half the cases; in fourteen men between 20 and 40 years, ten were antitoxic; between 40 and 50, nine out of every ten were so. He does not believe in a congenital susceptibility of diphtheria, but is firmly convinced that it is acquired by age and the constant irritation of the virus on the throat, eyes and other parts of the body. He tells that he obtained the most virulent in two healthy individuals!

Escherlich was also of opinion that the virulence of the bacillus did not determine the severity of the disease, as he had met with very light cases where the bacillus was virulent and *vice versa.*—*Med. Press.*

Simple Maxims.

Doctor, here are a few simple maxims for you to impress upon your humble patrons:

1. Maintain an invariable recurrence of defecation.
2. *Ingest* not that which will *digest* not.
3. Shun straightforward aerial influxes.
4. Keep your textile vesture in consistent relationship with your meteorological environment.
5. Let your prandial repast generously exceed the others.
6. Avoid intense luminous reflexes while poring.
7. Contemplate not the vinous product when it is ruddy.
8. Be non-excessive in indulgence through the entire category of things that be.
9. An intact intellect within a hale corpus is the *summum bonum*, with reference to all that most nearly affects you.—*N. C. Med. Herald.*

THE ATMOSPHERE AND LIFE.

Calculations based on observations of luminous meteors lead us to believe that the atmosphere is not less than one hundred miles deep, and may be two hundred. The laws governing the pressure of gases and the action of gravity tell us that it must in shape be an oblate spheroid with the poles markedly flattened, much more so, indeed, than is the case with the earth itself. Since it is able to support a column of mercury or water weighing about fourteen and three-quarter pounds in a tube with a diameter representing one square inch, it must press upon the surface of the earth at every point with about this weight. An ordinary-sized man bears constantly upon his body a pressure of about fourteen tons; but as this pressure is in all directions, and from within outward as well as from without inward, the compensation is perfect and reduces the actual pressure to practically nothing.

The breathing of plants and animals is the same. Not long since it was believed that animals only required oxygen and that plants required carbon dioxide. This was an error. Plants do not breathe carbon dioxide, but, like ourselves, oxygen. They, however, find by far the largest volume of their food in the carbon dioxide of the air. This they decompose by aid of direct sunlight, and by seizing upon the nascent carbon convert it into plant tissue, while the oxygen escapes into the atmosphere. Since they thus release far more oxygen than they require for themselves, the air is kept constantly pure by their good service. Because they provide an oxygen balance of this kind, and have ever done so, to them we are indebted for the character of our present atmosphere and its most marked difference from that of primitive times. They have during countless millenniums been free oxygen manufacturers. Beginning their work in an atmosphere that was oxygenless, they have gone on with their good services until it is now fit for the breathing of healthy human beings. The change from the wholly irrespirable air of early times to the perfectly respirable air of to-day has come through slow, insensible degrees. Step by step it has been transmuted into the fitness that has made possible warm-blooded, quick-acting and quick-witted creatures. Had the work of plants not preceded us we could never have been; and should they stop such work it would mean speedy extinction for us. Our lives are bound up in theirs and theirs in ours by a reciprocity so perfect that it is marvelous. Imagine two sets of machines so adjusted that the running down of one winds up the other and the stopping of either stops both, and you will have a partial conception of the intimate relationship of the two. Our breathing and the fires of our homes and workshops supply them with much of their daily food, and they supply us not only with food and clothing, but with pure air as well. Had the vegetable world succeeded in converting all the carbonic-acid gas of the primitive atmosphere into oxygen and carbon, the proportion of oxygen to nitrogen would have been much greater than it is. The weight, too, of the atmosphere would have been very materially increased and our coal beds would have proven far vaster than they are.

A very large part of the purification of the early atmosphere we must credit to the mineral world. It markedly diminished the atmospheric weight for us. In the burnt-up rocks of azoic times calcium and other such elements were left as oxides and hydrates. Now we find them forming mountain chains and immensely deep strata as carbonates, the greatest proportion of their weight having been absorbed from the air. Every bed of limestone, chalk and marble illustrates this point. The quantity of carbonic-acid gas these have absorbed from the air is so vast that if released again the world would no longer be fit for us to inhabit. One is almost constrained to believe that in this early absorption of the mineral world can be found a purposive act. It certainly looks as if eons of ages ago the way was being prepared for our advent. Every change led thitherward. Had the mineral world not absorbed the carbon dioxide, but left all the work to the plants, we might have had more oxygen than to-day, but we would likewise have had more pressure. This in turn would have required changes in the structure of our tissues that would have made such life as we now have impossible.—*Public Opinion.*

TREATMENT OF PERFORATION OF ROUND ULCER OF THE STOMACH.

At the Surgical Congress held at Lyons, M. Michaux spoke on perforation of round ulcer of the stomach and its treatment. The question, he said, of the surgical treatment of simple ulcer of the stomach has not yet been brought before an assembly of French surgeons, and he would like to say a few words on the surgical treatment in case of perforation of these ulcers. The following personal case was, he believed, the first successful intervention of the kind obtained in France:

In September, 1893, a laborer in the employment of a railway company was brought to the hospital, with the following history. On the night before, in lifting a rail, he felt an intense pain in the epigastric region, with sensation of something having given way inside. A half-hour afterward, the pain getting worse, the man drank a glass of wine; hardly had he swallowed it than the burning in the stomach became greatly intensified, and toward morning he vomited the liquid mixed with bile. When examined by the speaker, the man did not seem to be in a very alarming condition; the face was a little anxious, the pulse full (80), the temperature 100° F., the abdomen contracted, but the suffering was very acute. All these symptoms indicated a rent in the stomach or in the upper portion of the small intestine. An immediate operation was advised, and after some difficulty the patient gave his consent. An exploring incision stretching from the ziphoid cartilage to the umbilicus was made and the peritoneum opened; at this moment some vinous liquid, together with a small quantity of alimentary *débris* derived from the evening meal, flowed out. The incision was enlarged, the liver turned up with the hand, and high up under this organ and the diaphragm the operator perceived a small tear on the anterior face of the stomach within an inch of the cardiac orifice. An attempt was made to draw the edges together with suture, but the tissue was so friable that the stitches would not hold. A fold was consequently made in front of the perforation, which was hidden at the botton of the fold by a double line of silk sutures, and a piece of iodoform gauze was placed over the sutured part, conducting the liquid to the abdominal wound left open for safety.

The following days the patient was nourished by the rectum, and at the end of a week the iodoform gauze was removed. A fistula was the final result, but the patient, who for the first month was reduced to a skeleton, gradually gained flesh, so that at the end of five months he had attained a remarkable corpulency. At this time also a successful attempt to close the fistula was made, and to-day the man is at work again. The works, continued the speaker, of Cruveilhier, Rokitansky, Brinton, Debove, Bouveret, etc., have given us some very interesting statistics that he desired to recall to memory. Perforation of the stomach is a frequent complication (13 per cent.) of ulcer; it is observed more frequently in man than in woman after thirty, and is sometimes produced by an effort. A curious fact is that if the ulcer is most frequently found near the pylorus, the perforation is generally met with near the cardiac orifice.

How can perforation be recognized clinically? The chief symptoms are: Intense gastric pain, a sensation of burning, of something torn inside, increased by the ingestion of food, retraction of the abdomen, absence of dullness over the liver, and, finally, all the symptoms of localized or generalized peritonitis. Vomiting is rarely present. In the face of these facts, the necessity of prompt surgical intervention is constant. The operation has been already practiced in Germany by Czerny, Steinhal, Kriege, Nissen; in England by Hastings, Gilford, Howard, Morse, Maclaren; in Switzerland by Roux, of Lausanne; while in France the operation has been performed by Poncet, Le Dentu, Walther, and the speaker. The operation has been done in all 25 times. The first ten cases ended fatally; of the fifteen others five were successful, those of Kriege, Morse, Maclaren, Roux, and his own just described. The secret of success lies in the promptitude of the operation: it must be done within fifteen hours after the accident.—*Medical Press.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

IN THE NEW ORLEANS MEDICAL AND SURGICAL JOURNAL

for September Dr. Will H. Woods reports a case of

Hysterical Deafness and Otalgia Cured by Hypnotic Suggestion.

The patient was a hysterical young man, nineteen years old, who complained of increasing deafness in the right ear. No objective symptoms could be found, and after the first visit pain also was complained of.

Finding on inquiry from his brother that the patient showed other symptons of nervous derangement, the author tried to hypnotize him and found it satisfactory. Until he denied the possibility of a relapse the patient returned a few times for a repetition of the treatment, each repetition showing immediate transient effect. Finally denying the possibility of a recurrence the patient failed to complain of one.

The author thinks his case corroborates the statement of Prof. W. C. Wood that the benefit in these cases is solely due to impressing the patient, while in the hypnotic state, with the delusion that something has occurred to cure him.

Other articles in this number are "Progress of Surgery," by Dr. R. S. Hill; "Psoriasis," by Dr. William S. Gotthell, and "A Case of Congenital Malposition of the Kidney," by Dr. Augustus McShane.

IN THE BROOKLYN MEDICAL JOURNAL

for November appears a very interesting article on

The Treatment of Constipation in Cases of Tea Poisoning

by Dr. James Wood.

The author found 40 per cent. of these cases troubled with marked constipation and 15 per cent. with constipation alternating with diarrhœa.

Finding the secondary symptoms of the constipation important, a number of laxative and cathartic drugs were used, colocynth giving good results in many cases, but failing to be of permanent benefit so frequently that it was stopped and cascara used in its stead.

The treatment adopted was as follows: A purge of eight grains each of calomel and jalap was given at night, and followed by from one half ounce to one and a half ounces of Rochelle salts, to completely empty the bowels. For several days the patient was kept without other food than hot milk, and given two grains of caffeine and eight of sodium bromide every four hours.

The certainty of a relapse of tea drinking, if not guarded against, was recognized, and the patient warned to use neither tea, coffee nor any kind of liquor.

Cascara is now ordered in doses of fifteen to forty minims every four hours, and by degrees the dose is increased and the interval lengthened until one half drachm to one drachm given at night will insure one or more free passages daily. On account of its palatability the author chose the aromatic elixir or aromatic fluid extract of cascara.

As soon as regular movements of the bowels are established the following prescription is usually written:

Insp'sated ox bile (pure Merck)....	℥ij
Sulphate of quinine.....	℈j
Sulphate of strychnia.....	gr. j
Extract of cascara sag.....	℈j
Extract of euonymus.....	℈ij
Extract of gentian..... ..	q. s.

Divide into 40 capsules and give two night and morning.

The ox bile is intended to prevent intestinal putrefaction, to stimulate peristalsis, and hasten absorption, and being absorbed assist the formation of more bile. Fowler's solution is often given with benefit at this stage.

It is advisable to continue treatment for some time after improvement is noted, and the author gives the following tonic pill:

Strychninæ sulph....	gr j
Caffeine mur. . ..... }	āā ʒj
Ext. damianæ..... }	
Cocaini mur.....	℈j
Ext. tanaxaci.....	ʒss

Divide into 20 pills and give two daily.

The caffeine and damiana act as tonics to the spinal centers; the cocaine is only used when there is a hyperæsthesia in the solar plexus causing a sinking sensation.

In a previous article by this author the symptoms of the over-use of tea were given as constipation, neuralgia, insomnia, hallucinations, palpitation of the heart, and other symptoms of general nervous and cerebral irritation, and the fact was noted that when green tea was used the symptoms of intoxication were much more severe than if the black variety were chosen. This was mainly due to the green tea containing a larger amount of volatile oil, which the black loses in drying by heat.

Physiologically caffeine is shown to differ greatly from theine in its action on the heart, splanchnic plexus, etc., but to coincide to a certain extent in its effect on the brain, kidneys, etc.

This explains, the author says, the unsatisfactory results often found after the prescription of caffeine; damaged tea leaves are deprived of their alkaloid, and the latter, theine, sold as caffeine. True caffeine seems to be a physiological antidote to theine in regard to the heart.

The first article appears in the *American Medico-Surgical Bulletin*, page 1028.

Dr. Arthur Clarence Jacobson reports a case of diabetes mellitus, interesting because the amount of urine passed is not above the normal (diabetes decipiens), and because the first symptoms appeared after the age of 59 and the patient a woman.

IN THE TEXAS SANITARIAN

for October, Dr. Frank S. Parsons discusses

The Treatment of Pneumonia in Children.

Dividing this affection into the two great varieties, croupous and catarrhal, the author recognizes in croupous pneumonia an acute, self-limited inflammation due to a specific organism, pneumococcus, but does not think the anti-pneumotoxin of the German investigators can be put to a practical use in treatment. He does not think a croupous pneumonia can be absorbed by any means, but seems to refer to those cases which have passed the first stage.

The greater disturbance shown by children with pneumonia is thought due to the comparatively small size of the alveoli compared to the bronchi.

The indications are to produce elimination and consequent reduction of temperature by diuresis and diaphoresis, to lessen coagulation by increasing the alkalinity of the blood, and to relieve restlessness and promote sleep. All of these indications seem met by liquid Dover's powder, spirits of nitrous ether and acetate of potash. A large, well-ventilated room, slightly darkened and at about 70° F., is the best sick-room, but of course often unobtainable.

To avoid shock the author uses a warm bath instead of a cold one, and also prefers aconite to veratrum and dislikes the use of coal tar antipyretics. Purgatives and expectorants seem injurious.

Nitro-glycerine is mentioned as useful in preventing cardiac failure by capillary resistance. The author seems to think belladonna also will dilate the capillaries.

Catarrhal or broncho pneumonia is more common in infants than the preceding variety, and the author treats these cases in a different manner. The child is wrapped in a long nightgown of cotton flannel and has a thick chest protector of the same applied. Chloral hydrate is the favorite antipyretic, and to increase and liquefy the secretion a kettle of water with or without turpentine is kept boiling in the room. An expectorant mixture being usually required, some combination of ipecac, usually with opium, is preferred, and the following seems satisfactory in most cases:

Vin. ipecac	f 5j
Potass. acetatis	3ss
Tr. opii camph	f 3ij
Elixir simplicis	f 5j
Aquæ destillate q.s.	f 5iv

S.: f 5j every two hours for infant six months old.

To free the stomach and intestines of mucus a little calomel, or, the author says, a solution of hydrozone, one teaspoonful to one half pint of water, is useful.

Digitalis may only be used in the later stages of croupous pneumonia, but may be used with or without whisky at every stage of the bronchial variety.

Dr. Matthew M. Smith reports a "Monstrosity Born Without Limbs or Sexual Organs," and living for twenty days, finally dying from neglect.

Other members present had seen infants without sexual organs and without the long bones of the limbs, but none knew of a case similar to the one reported.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

The Modern Treatment of Diphtheria.

Fischer, of New York, contributes the following conclusions to the *Post Graduate:*

1. Local disinfection—careful, distinct nasal antisepsis by means of naso-pharyngeal irrigation; this can be done by irrigating with warm salt water (1 drachm to the pint); the addition of bichloride of mercury (1 grain to the pint), or of borax (1 to 2 drachms), or acid salicylic (4 grains to the pint), is regarded as an improvement by some. It should be thrown with enough force to flow out of the other nostril and partly by the throat. Tearing the membrane by using force will cause epistaxis, and is not advisable. Jacobi says in his treatise of diphtheria (page 208): "When they see benzoate of sodium destroying bacteria in a glass vessel, they take it for granted that the human system will permit of the same action as a glass vessel. Thus benzoate of sodium is sent into the stomach or pulmonary artery under the order to do the same as it does in the laboratory. The drug has, in consequence, had a short life, after having been extolled in a very limited time by microscopists," etc.

Jacobi concludes by saying that as an antidiphtheritic or antipyretic it utterly failed. Frequent applications of pepsin, trypsin or papayotin with a medicine dropper may be indicated in some abstract cases. Naso-pharyngeal irrigation will cause the neighboring enlarged glands to become reduced in size quicker than all other treatment combined.

2. Sponging with peroxide of hydrogen hourly.

3. Internal administration of stimulant drugs—ferric chloride for tonic effect. Alcohol, no matter at what stage, is indicated in all cases of septicemia, be they diphtheritic or not.

4. Liquid diet—milk, beef-tea, milk-punch; rectal feeding if necessary.

5. Local applications of cotton swabs moistened with bichloride (1 to 1,000 to 1 to 500), applied with great pressure every two hours, as an abortive plan of treatment, if the case is seen early.

6. Antipyretics. If at all useful, salicylate of sodium is the best, in doses of 2 to 15 grains

every two hours or more, according to the age and tolerance of the patient. If the drug is not well borne, antipyrin or antifebrin may be given.

The temperature in uncomplicated cases of diphtheria has given little trouble, except when complicated by scarlatina. Cold applications—cracked ice and ice cream—are very grateful to patients.

Calomel, to empty the bowels and reduce the temperature, is a mercurial salt, besides being a valuable intestinal antiseptic. Orange and lemon juice are also highly beneficial. The complications and their management must be considered in each case. So must the question of intubation and tracheotomy, to which the author only refers. Every case must be studied, and the treatment based on the previous habits, the general condition, the severity of the attack and the amount of the infection.—*Fort Wayne Med. Mag.*

Effect of Mercury on the Kidneys.

Welander (*Hygeia*) has had the opportunity of observing ninety-seven cases of syphilis before treatment with mercury and during the administration of the drug. He found that its elimination was accompanied by a greater or less irritation of the kidneys, manifested by casts in the urine. These casts increase in proportion to the length of the treatment, gradually decrease after its cessation, and generally disappear within a month or six weeks. No injury to the kidneys, either temporary or permanent, was observed.—*Universal Medical Journal.*

The Treatment of Whooping-Cough with Quinine.

Baron (*Berliner klinische Wochenschrift*) reports on fifty cases of whooping-cough treated after the old manner of Benz-Ungar, which they advocated in 1868. In a few children the good action of quinine was noticed in two or three days, but in most of the children the results were shown after several days.

The first evidence of value is the lessening of the night attacks. The improvement continues until health is restored, unless the dose be too suddenly reduced. The author continues the administration of quinine for three weeks. Relapses do not occur in children treated with quinine. In spite of the fact that the quinine was not given as regularly as directed in more than half the cases, there were only two failures noted. The treatment is of unusual value in the cases of acute inflammation of the lungs caused by the whooping-cough.

Since the thorough trial of quinine, whooping cough has lost all its terrors to the author.

The proper dose of quinine is one-sixth of a grain for each month of the child's age, and one and a half grains for each year, given three times in the day, at 6 A.M. and 2 and 10 P.M. More than six grains three times daily is not necessary for older children. As the case improves the number of daily doses is decreased.—*University Medical Magazine.*

The Treatment of Typhoid Fever.

Osler, of Baltimore, in discussing the treatment of typhoid fever at a recent meeting of the Clinical Society of Maryland, said he thought that the antipyretic drugs were entirely superfluous in this disease. The cold bath is more efficacious, but is not always available in private practice; but all the good effects of the bath can be obtained by sponging. A good nurse or doctor can sponge the patient so effectually that the fever will be satisfactorily reduced. When the temperature is high ice sponging—not with ice water but with lumps of ice—over the back and legs will reduce the temperature very pleasantly to the patient and satisfactorily to the doctor. Delirium and stupor are also effectively treated by ice sponging. The use of antipyretics in typhoid fever is, in nine cases out of ten, positively hurtful. They reduce the heart's action and cause weakening sweats, and their use is an unmitigated evil. In the great majority of cases the treatment may be taken from old Dr. Nathan Smith, of Yale, which was pretty much that of to-day. Plenty of fresh air, liquid diet and cold externally. He was in the habit of turning out the friends of the patient, putting the patient on the floor and then dashing water, handed through the window by an assistant, over the patient.—*Canadian Practitioner.*

Mechanical Insufficiency of the Stomach.

According to Boas, the expression ectasis, or dilatation of the stomach, is not in accord with the present stage of science. The determination of the size of the stomach is no criterion whatsoever for the disease "dilatation of the stomach," since it is almost impossible to obtain a correct opinion of the size by the different methods at present in use, because a stomach which is easily extensible can rid itself of its entire contents, whereas one which can only be extended with difficulty will never become empty. Fortunately this method of examination is not the only one at our command—the fluctuation of the stomach, the gurgling when the organ is empty, the presence of peristaltic or other movements, diminished urine, thirst, severe constipation, copious vomiting, and previous history, are much more important than the determination of the size and position.

In the diagnosis the most important point is not whether the stomach lies higher or lower, or whether it is smaller or larger, but what it is able to accomplish. Instead of the expression "dilatation of the stomach," "mechanical insufficiency" should be used.

What method is there for diagnosing the presence and degree of a mechanical insufficiency? The best way is to determine whether the stomach will rid itself of a meal of known quantity in a specified time. It is best to examine the stomach in an empty condition. Give the patient a supper of cold meat, white bread and butter, and a large cup of tea given at eight o'clock in the evening. A normal or slightly atonic stomach will completely get rid of such a meal during the night, but if the motility is greatly re-

duced, certain portions of the meal will remain in the stomach, and the contents can be examined in the morning as to their quantity, acidity, and process of fermentation. If the stomach constantly shows such masses, which have usually undergone fermentation, a severe motor insufficiency is undoubtedly present. If the stomach is empty after such a meal it is either entirely healthy or only slightly insufficient.

We can recognize two degrees of mechanical insufficiency: the first, or slight, and the second, or more severe insufficiency. These two degrees can be separated as regards course, prognosis, and treatment.

The course of a mechanical insufficiency of the first degree, which is called atony, is a chronic one; the symptoms are less characteristic and are those of a chronic dyspepsia; vomiting, if present at all, is slight, and it never contains products of fermentation. In such cases it can be shown that the stomach works slowly, but still empties its contents completely. The chemical examination of the contents of the stomach is of less importance than the microscopical; by this it is seen that the characteristic sarcinæ are only rarely present, bacteria are scanty. The bowels are either slightly costive or normal. The prognosis of this degree is not bad, as cure is frequently effected.

The forms of mechanical insufficiency of the second degree, as far as they are not due to stenosis of the pylorus, are caused by irregular living or excesses in eating and drinking, and in these the prognosis is much worse, the most dangerous symptom being inanition Cures may, however, take place even here.

In the treatment the stomach must have as much rest as possible. In insufficiency of the second degree carbo-hydrates and fats should be restricted. Massage, faradization, and hydro-therapeutic measures may be successful. In severe cases, the stomach must be washed out, antifermentative remedies given, and the patient fed per rectum. Salicylic acid especially is of great importance.—*American Medico-Surgical Journal.*

The Frequency of Renal Albuminuria, as Shown by Albumin and Casts, Apart from Bright's Disease, Fever, or Obvious Cause of Renal Irritation.

Shattuck (*Boston Medical and Surgical Journal*) has examined the urine of patients seeking his advice for various ailments. He has used it boiling with additions of nitric acid and the Heller test, and considers them the most satisfactory.

He concludes his article as follows:

1. Renal albuminuria, as proved by the presence of both albumin and casts, is much more common in adults, quite apart from Bright's disease or any obvious source of renal irritation than is generally supposed.

2. The frequency increases speedily and progressively with increasing age.

3. This increase with age suggests the explanation that the albuminuria is often an indication of senile change.

4. Though it cannot be regarded as yet absolutely proved, it is highly probable that faint traces of albumin and hyaline and finely granular casts of small diameter are often, especially after 50 years of age, of little or no practical importance.—*University Medical Magazine.*

Diabetic Coma.

From observation in 400 cases of diabetes, Kulz found that numerous casts appeared in the urine before and during diabetic coma. Only a minimal amount of albumin was present as a rule. The occurrence of casts in the urine is, however, of great importance, and a noteworthy prognostic sign of approaching coma. No difference was noted in the number of casts, whether the coma terminated fatally or in temporary recovery. With the disappearance of symptoms of coma, the casts vanished from the urine. Sandmeyer also made a communication on this subject at the German Congress f. innere Medicin in 1891. In 20 cases of diabetic coma he found numerous casts in every case. They were present when the prodromal symptoms occurred and also when the coma was marked.—*Braith. Retrosp.*

The Cure of Progressive Paralysis.

Marro and Ruata, Royal Academy of Medicine in Turin (*Gazz. degli Osped*): The speakers presented a man and a woman who had been treated for progressive paralysis, one being quite cured since three years, the other since one year. The mode of treatment consisted in causing the formation of subcutaneous abscesses in various places on the back along the spinal column, by means of cantharidate of potassium injections in the man, and essential oil of turpentine in the woman.

During the discussion, Lombroso stated that he thought the recovery due rather to the general febrile state induced by the injections than to the formation of abscesses. He recollected having seen several recoveries from progressive paralysis after the occurrence of small-pox, and confessed that he had once artificially caused small-pox in a patient, this measure being followed by recovery.

Marro said he would not insist upon the exact explanation of the curative process, and would merely remind his hearers that in variola there was an extensive suppuration. Lombroso asserted that he could call to mind a case in which the patient had been cured after an attack of typhoid, in which there is no suppuration.

Nitro-Glycerine in Sciatica.

Dr. Lawrence (*Revista de Ciencias Medicas de Barcelona*) reports the case of a carpenter of fifty-two years, who suffered for several weeks with sciatica. In order to alleviate the pain he had become a morphine user and could not abandon the habit. After trying a multitude of drugs he gave him a 1:100 solution of nitro-glycerine, one drop three times a day, gradually increasing the dose to five drops. Relief was almost immediate, and in ten days he could resume his work, completely cured. —*Lancet Clinic*

Relation of Tuberculin to the Blood Cells.

As the result of recent experiments, Dr. Maurel finds that tuberculin, in the doses in which it is already employed therapeutically, has no sensible effect upon either white or red blood cells. His experiments also show that human leucocytes are able to resist successfully the bacillus tuberculosis, and that it is only necessary to attenuate the bacillus to a slight degree to enable the leucocytes to destroy the microbe. The experimenter suggests that it is only necessary to discover some agent capable of doing this to cure one of the most dreadful maladies with which the human race is afflicted.—*N. O. Med. and Surg. Jour.*

Treatment of Syphilitic Dyspepsia.

Pasquale de Tullie (*Il Policlinico*), after stating that three-fourths of the population (? of Naples) are infected with syphilis, proceeds to quote a number of recorded post-mortem observations of syphilitic lesions, mainly ulcerative, of the stomach. He points out that in certain cases of syphilis symptoms of gastric dyspepsia are prominent either soon after primary infection or at a later date. He finds that the free gastric acidity and proteolytic power are diminished in these cases. The exhibition of the green iodide of mercury gave excellent results. It had, apparently, not only a general but also a topical action upon the secreting structure of the stomach. The quantity given was about half a grain in divided doses during the day. In some of the cases the patient took as much as thirty grains before recovery was complete.

SURGERY.

Contribution to the Study of the Etiology of Varicocele.

B. S. Talmey, M.D., in the *American Medico-Surgical Bulletin*, is quoted as saying that masturbation is almost always the pathological cause for varicocele. There can scarcely be a greater unnatural irritation of the nerves than that caused by onanism. During such an irritation the testicles being in a secretory condition are supplied with a greater amount of blood, and anything that increases the amount of blood to the testicles is surely a cause for varicocele. Through the continued high pressure the walls of the vein become lax, flabby, and unresisting and the vessels enormously dilated. The elastic and contractile tissue of the venous walls is absorbed and replaced by a low grade of connective or fibrous connective tissue. The same condition as in the spermatic cord in the male is found in the broad ligaments, as the ovarian veins in the female are the analogue of the spermatic veins in the male. That varicocele is frequently formed in women after pregnancies is agreed by most writers on this subject. But the author does not remember having read about a case of varicocele in a virgin such as he once saw in a girl, whom he immediately suspected of masturbation. The sexual organs were all in a normal condition, and yet she complained of a dragging sensation along Poupart's ligament and in the vagina. The broad ligaments were thickened.

Eczema of the Hands in Surgeons.

At the Twenty-third Congress of German Surgeons, according to a report published in the *Gazette Hebdomadaire de Medecine et de Chirurgie*, Dr. Lassar stated that, in his opinion, the eczema of the hands frequently seen in surgeons was produced by antiseptics, which, although they caused cutaneous alterations which were hardly appreciable, were yet sufficient to explain the particular sensibility of the skin. This, he thought, was the reason of the frequency of relapses. As to the treatment, all that was needed to cause the eczema to disappear was to change the antiseptic often. As a preventive, he recommended rubbing the hands, after washing them with soap, with a mixture of equal parts of vaseline, lanolin, olive oil and glycerin. Dr. Rotter recommended an ointment composed of from one to two parts of formol, one hundred parts each of zinc oxide and talc, and two hundred parts of vaseline.—*N. Y. Med. Jour.*

Anesthesia by Cocaine Deprived of its Disadvantages by Trinitrine.

Dr. Gautier (*Wien. Med. Presse*) recommends the addition of trinitrine to solutions of cocaine in order to render anesthesia by this drug innocuous.

Cocaine muriate.....	3 grains
Alcoholic sol. trinitrine.....	10 drops
Distilled water.....	2½ drachms

A hypodermic syringeful of this solution contains one-third grain of cocaine and one drop of the trinitrine solution. He has used this solution for two years without the slightest disadvantage. Thomas, of Marseilles, has employed this same solution in anesthesia of the fauces and larynx. In three cases where a ten per cent. solution caused grave symptons of poisoning this preparation was used with success. In all cases it was well tolerated. His solution was made according to the following formula:

Muriate of cocaine.....	45 grains
Alcoholic sol. trin. (1:100).....	40 drops
Distilled water.....	1 ounce

Local applications to the pharyngeal or laryngeal mucous membrane does not produce the well-known sensation of dryness which is usually observed with the use of cocaine, but an agreeable feeling. Trinitrine does not appear to reduce the anesthetic and vaso-constrictive action of cocaine.—*Lancet Clinic.*

Lesions of the Stomach Simulating Cancer.

In Paris lately, M. Ferrier drew the attention of his colleagues of the Surgical Society to a form of gastric disorder simulating

cancer, which was much ignored in a surgical point of view in France. A woman entered the hospital with gastric trouble, presenting all the symptoms of cancer and coinciding with the existence of an epigastric tumor. M. Ferrier performed laparotomy for exploring purposes, and found the stomach adherent to the walls of the abdomen and to the left lobe of the liver. After breaking down those adhesions, the operator closed the wound, and the patient gradually lost all bad symptoms, and left the hospital quite recovered. In concluding, M. Ferrier said that in many cases, purely inflammatory lesions could simulate cancer, and an exploring operation would put the case in its true light and do no harm to the patient.—*Med. Press and Circular.*

Treatment of Hydrocele.

A letter from France to the *Med. Press and Circular* says that the classical treatment of hydrocele, puncture and injection of tincture of iodine or some other irritating liquid, has been rendered much more simple by a surgeon who has published the result of several cases cured rapidly by the method. He inserts the trocar into the most dependent part of the tumor and removes the liquid; he then injects a five per cent. solution of carbolic acid, which is removed almost immediately. The trocar is introduced a second time into the canula, and pushing it up toward the highest point a counter-opening is made. The trocar is again withdrawn, and a drainage-tube is passed through the canula and left in position, the canula being removed. The patient can immediately get up and walk about. The drain is withdrawn on the fourth day, and in a week the man is cured.

Odd Methods of Syphilitic Inoculation.

Dr. W. Judkins (*Jour. Cutan. and Gen.-Urin. Dis.*) says syphilis is so widespread and contagious that it is rather surprising that it claims no more innocent victims than it does. The author now reports two cases contracted in barber-shops, one from the use of the hair clipper and one from a papular syphilide of the barber's hands.—*St. Louis Clinique.*

BIOLOGY.

Is Biliary Lithiasis of Microbic Origin?

This question was discussed in a paper by A. Gilbert and S. A. Dominci at the last meeting of the Society of Biology. Since Galippe in 1886 showed the presence of micro-organisms in biliary calculi the question has remained in abeyance until taken up by the authors. They have examined calculi from six cases. In two cases in which the lithiasis was of recent date they were able to demonstrate by coloration and culture the presence of organisms in the center of the calculi.

In two cases in which the lithiasis was of ancient date, examination yielded only negative results. In one case in which the lithiasis was of equally ancient date, cultures yielded only negative results, but in colored sections microbic forms were discoverable. In another case where old and recent calculi existed together, the first gave negative results, but the second, on the contrary, gave positive results, both in examination of sections and by cultures. Where culture succeeded, the organisms which developed belonged to the coli-bacillary species. These results are explainable by two hypotheses.

First, it may be assumed that the formation of calculi has preceded their invasion by bacteria, and this hypothesis is the more tenable from the fact that in cases where calculi contained the coli-bacillus the bile was infected with the same germ.

On the other hand, it may be assumed that the infection by the coli-bacillus has formed the initial stage from which this lithiasis has proceeded.

The authors adopt the second of these hypotheses. They have tried to verify the theory of the microbic origin of biliary lithiasis experimentally, and with this object they injected into the gall bladder of three dogs cultures of Eberth's bacillus and into the gall bladder of one dog Escherich's bacillus. Of the animals inoculated with the first-named bacillus the first succumbed at the end of a month with a suppurative cholecystitis and double pneumonia. The second died in three months without lesion of the gall bladder, and with a magnificent (*sic*) vegetating endocarditis of the mitral and tricuspid valves. The third was killed after three months, as also the animal inoculated with the coli-bacillus, but nothing was discovered after death. The experiments, under different conditions, are to be pursued by the authors.—*Med. Press and Circ.*

A New Process to Conserve Fresh Milk.

This new method of preserving milk is original, and, it is said, very effective. Large cylinders are partly filled with the milk, after which oxygen is forced into the cylinders at a pressure of two atmospheres. This procedure entirely sterilizes the milk, which may then remain for months in the cylinders without undergoing any change. It can be sent on long voyages with perfect safety. When it is wished to use the milk the gas is allowed to escape, and the contents of the cylinder are then found to be just as sweet as when first put in.

THE following micro-organisms have been found to be eliminated from the system by the liver through the bile: The bacillus of glanders, the bacillus of typhoid fever, the spirillum of cholera, the bacillus coli commune, the bacillus of anthrax, the staphylococcus pyogenes aureus, the bacillus pyocyaneus, Friedlander's pneumococcus and the bacillus murisepticus.—*American Medico-Surgical Bulletin.*

ORIGINAL ARTICLES.

INFLAMMATORY DISEASE OF THE UTERUS AND APPENDAGES UNDER VARIOUS MODES OF TREATMENT.

JOSEPH PRICE, M.D., Philadelphia.

The methods of treatment of pelvic disease may be broadly classed as those that are proven and those that are experimental. Proven methods have gained their position from the work of earnest, painstaking surgeons who step by step have arrived at conclusions which to them are as irrefutable as any of the laws of physics or mechanics, and from which they are not induced to vary save by the exigencies of a given situation, and then only to graft a new step or unusual procedure on account of some complexity which the case offers. In opposition to these we have the experimental surgeon, who seeks new laurels in the line of new microbes and new ways of killing them after he has discovered them. After this death-dealing agent has been discovered, and with it some new chemical antidote, his next ambition is to invent some new automatic instrument by which all surgery becomes self-regulating. The abdominal wall is stitched up as if by a Wheeler & Wilson, and a new table fitted with a crank and a watch-tower, with red lights and electrical attachment, signals danger, but don't tell them to stop. Of all this what is to come? With the minor steps condemned and the question of the legitimacy of the simple removal of the appendages even questioned, the advance guards of automatic surgery would have us leap the gulf and add to the original operation something to simplify it. What delicate irony! What sophisticated reasoning! Surely the refined metaphysics of the scholastics were not more disconcerting than this—and not less rational.

We must start out on the broad ground that simplicity of work must give us perfection of results; that the less we primarily deal with the less is the restoration to be made, assuming always that we deal always with diseased structures and do all that is necessary for their removal or ultimate recovery. All methods that do not thus aim at completeness must fall under the ban of criticism.

What is the rule with reference to disease anywhere of a suppurative character? The suppuration must either be encouraged to evacuate itself or assisted to an egress. So it is in the liver, the kidney, the brain. So it must be in the pelvis. Any method that loses sight of this principle must also fail in its ultimate efficiency. Herein is the failure of most, if not all, of the so-called conservative methods so loudly heralded. In all suppurative disease there is concurrent inflammation, and the part originally diseased is glued down on some neighboring structure, interfering with its function or with its anatomical relation, causing pain or discomfort, greater or less. It is argued by the conservative camp to take away just as little as possible, leaving adhesions if necessary to simplify the work. This to the thorough surgeon is not permissible. His aim is to remove disease and to bring the parts not diseased into

their normal anatomical relation, and by so doing conduce more certainly to the ultimate well-being of the patient. From this point of view the operation that would remove a diseased tube and leave an ovary bound down by adhesions to the pelvic wall or to the intestine or omentum is not surgery at all; it is only experimental shilly-shally which, if it results well, is no credit to any one.

The same may be said if the method is applied to the conservation of a useless tube because it is hard to remove. To know that these cases may get well if we leave them when we have opened the abdomen to find them, puts our conservative in the light of doing a useless operation, and at once becoming conservative because it is the easiest thing to do. To leave a tube full of pus or blood, simply because it is hard to remove, is like building a bridge till we get into deep water and then completing it with a ferry-boat. The so-called conservatism has no right at the present time to argue from the standpoint of the infancy of abdominal and pelvic surgery, any more than the fogy who stays at home would have a right to justify his fears of travel by citing the dangers of sailboat travel as an argument against the ocean liners of to-day. To say that many ovaries have been removed which ought to have been saved is to say what we all know. Cures by operation have been sought where the procedure was not justifiable. We know that such errors were a part of the pioneer work—accidentally of the best men, designedly of the seekers after notoriety. But this does not answer the surgery of to-day; neither is it a fair accusation nor a plea. It is simply special pleading in the line of popularity. It is a fad which, like electricity, tickles the popular ear, the uncritical eye and the easily satisfied imagination.

The surgery that leaves pus tubes and abscesses to get well of themselves and afterward finds pregnancy occurring is so fabulous, mythical and mystical that I prefer simply to wonder without caring to understand or believe. If we are to have miracles and magicians with wonder-working tricks, let us swallow them whole, not try to digest, but lie stupid till they have worked their way through.

What I have here referred to incidentally leads to a broader reference to pelvic pathology. To understand the limitations of conservatism, especially as applied to subsequent conception, it is necessary to consider the complexity of the pathological processes which militate against every chance of the organs regaining their physiological function. Pus tubes are not simple. It is the rule to find them with multiple constrictions and with the tube simply a wire line, its lumen a wreck. The history of the changes leading to this condition of things is often of the utmost importance in diagnosis. The earlier, non-operative period when the clinical and post-mortem conditions which were carefully noted, as in the researches of Bernutz and Goupil, have put us on the correct line of investigation and have taught us what to look for, where to look and how to distinguish necessary operative conditions. Studies in intestinal surgery and in the general physiology and anatomy of the intestinal tract are necessary for correct performance of this work, and the more general success of all sorts of abdominal operations at the present day is secondarily due to the wisdom of accrued experience and to the advances made in intestinal surgery with which pelvic surgery has so much in common.

Many of the operations now successful were formerly failures because of the insufficient knowledge of how to deal with wounded gut, how to make an anastomosis or to do a bowel resection. Hence it is to be put down as a postulate that no man has a right to attempt pelvic surgery who does not know how to deal with all the complexities of intestinal surgery. To know when to stitch and when not to stitch intestine is as necessary as to know when to operate and when not to. Incomplete work, here as in all other divisions of the art, is fatal to good results. A fecal fistula is often the result of careless handling or of inexcusable carelessness in passing over a bowel lesion. That we may tear an intestine is no reason for leaving an adhesion which may afterward cause bowel obstruction, and it is an undisputed fact that many of the bad after-results are due to carelessness in this respect alone.

The leaving of pus tubes to recover of themselves is just one step removed to stuffing them with gauze and trusting to Providence. To puncture, evacuate and stitch a suppurating cyst, say a real ovarian cyst, would be derided out of

sight, and yet we now have a set of operators who do not hesitate to do this with the smaller pus tube, smiling as they exercise the prudence which is the better part of their valor. I do not hesitate to say, and to say positively, that the men who descend to this sort of work are those who in their earlier history have been guilty of extreme rashness and now are hiding behind extreme prudence—so called. Take them one by one and look into their work, and you will find something in it that is frightening them now. All the so-called operations for room and light point to confidence insufficient to trust to a cultivated tactile sense. The removal of the sacrum for an ovariotomy or pelvic operation is no more justifiable or necessary than the resection of a rib for a simple pleurisy. Extreme resorts are in general the expedients of BAD SURGERY, which has lost its delicacy and seeks to take the disease by storm.

I cannot refrain from here paying my compliments to the Trendelenburg position in this connection, and saying that I find it just as useless in all abdominal surgery as it is for the operation of suprapubic cystotomy for which it was invented.

The various modes of treatment that have been suggested are scarcely to be noticed. They must stand or fall by their results. It is fair to assume where great results have been claimed, but the means have been problematical, that the disease was slight or imaginary; and so where some mechanical procedure, such as the Trendelenburg position, is said to have simplified and rendered easy all the difficulties of pelvic surgery, I must allow those to believe it who find the need of it, and say "*Credat judaeus apelles non ego.*" I put it down that the long incision and elevated position are not necessary, because with a minimum of incision and real surgical care the conditions that presumably demand them do not exist, and the advantages they offer are therefore mythical. I am willing to acknowledge that if a man has india-rubber or frozen fingers he can feel nothing; and that if he is blind and cannot feel he is not fitted for a surgeon; but I confess, moreover, that I am in no position to sympathize with such sufferers.

A word with reference to the assertion that with the Trendelenburg position there is no escape of fluid into the abdominal cavity. If there is a collection of any kind in the tube, not over-distended, and the pavilion is attached to the ovary, it is an easy matter to enucleate the mass without rupture, but if the pavilion is attached deep down on the pelvic wall or to an intestine, what is to become of the discharging fluid? It is very easy to manufacture reasons that will not explain at all in the actual conditions of things. Any operator or set of operators who argue from a condition of affairs different from the above are taking a stand upon insufficient data.

Akin to all these undemonstrated claims are the tentative methods in certain conditions, such as gauze-packing and vaginal puncture for tubal abscess. Now it is a demonstrated fact that gauze does not drain anything but mere fluid matter; the *débris* of any sort whatever remains behind, and in the cheesy conditions which obtain in pus collections, it is a matter of utter impossibility to clean out the cavities by such packing. Then, again, the vaginal puncture is as uncertain as can be any procedure that does not reach to the bottom of the disease. Primarily we do not know the extent of the disease, nor its surroundings, nor its complications, and therefore we cannot drain it certainly by any one given puncture nor by any method save enucleation. After the enucleation is made the general cavity can be drained, and the results are in no wise questionable.

What shall we say as to the removal of the entire uterus in the presence of tubal and ovarian disease? I take it that if all the pathologists who have ever examined uterine structure—which is in great part muscular—were to make a report, there would be a consensus of opinion than an abscess condition of the uterine walls, apart from a broken-down fibroid, is the rarest condition imaginable, save at the cornua, in case of pyosalpinx. The disease here is strictly definable and removable. It is an unjustifiable assumption to assert that the uterus is diseased and is the reason for the failure of cure in certain women whose appendages have been removed. To remove, therefore, an organ which in a great majority of cases is not even remotely diseased is a seeking after means to obviate predicated bad results which could not be otherwise explained. When men are on record as saying that it is impossible to remove tubes and ovaries without leaving some ovarian tissue, do we go very far astray in thinking that they must

also leave diseased structure sufficient to cause trouble or that their methods are otherwise imperfect?

Again, the arguments for this ultra position all come from sources prone to bemoan bad results. It must be remembered also that there is a difference to be noted in the cases from which they would assume their data. The disturbances due to fibroid tumors are developed at a rather late period, while those necessitating the removal of the appendages are of earlier origin. Hence it is nonsense to argue that the condition of the patients should be similar. If the trouble, nervous or otherwise, is no greater in a woman after operation than it would be at the menopause, are we justified in doing a hysterectomy on every woman whose tubes and ovaries are diseased? I think not. To argue that we need not do an entire hysterectomy, but may leave the cervix, is the weak answer of an uncertain position. The cervix, of all parts of the uterine structure, is most prone to malignant degeneration, and this one fact would be the most sensible standpoint from which to argue the total ablation of the uterus in cases in which the operation would otherwise be indefensible.

In conclusion, we are to remember that enough has been done of all kinds of pelvic work to decide the general trend of results; how far they are satisfactory and how far disappointing. The end should justify the means, not in the hands of the disappointed experimentalist, but in those of the careful, painstaking surgeon; one with a conviction and a faith born of experience and care; one who each day balances his accounts with himself, not seeking to escape the onus of a failure by a flight into unknown seas; who gathers himself together, makes no one mistake twice, and evolves a system which is not of dreams but of reality, and which bears a harvest of results which need no explanation nor apology.

TREPHINING IN HEAD INJURY WITH PARALYSIS OF OPPOSITE ARM FOLLOWED BY FUNGUS CEREBRI.*

R. M. HARBIN, M.D., Calhoun, Ga.

Since apparently trivial injuries to the head are so often followed by unfavorable results both immediate and remote, we are led to consider them more carefully with reference to radical treatment, and it is from a study of cases that do not do well that we derive more practical information. Among the immediate dangers of head injuries to be considered are symptoms of compression, paralysis, inflammation of brain substance and abscess, and among the remote dangers are atrophy of muscles, insanity and epilepsy.

I have a case to report, and my reasons for doing so are that it is a typical case of head injury, furnishing a distinct indication for operative interference, and that it is a striking example of the practical value of the applied rules of topographical anatomy of the brain.

W. S., aged twenty-five, whose previous health and family history was good. Was called to see him December 15th in consultation with Dr. J. H. Malone, from whom I obtained the following history. Three days previous the patient in a fight was struck upon the head with the heavy end of a thirty-ounce billiard cue and was carried home in an unconscious condition. His wounds were dressed and he revived to a half-conscious condition in two hours, having vomited a number of times. There were a number of wounds about the scalp, but only one was of any serious consequence, and it was a gash about two inches long, on right side, extending from median line at a point about two inches anterior to middle point between occipital protuberance and root of nose, extending outward and backward. He complained of intense throbbing headache at locality of wound and was very restless and irritable, although able to sit up.

I saw him on third day after injury and found above symptoms aggravated, with his opposite or left arm completely paralyzed, sensation being normal. His pul-

*Read before the Georgia State Medical Association, April 20, 1894.

sating headache made him prefer to sit in an elevated position; pupils were dilated and pulse subnormal, varying from 48 to 60, and temperature normal. A saline purge was given and then bromide and ergot with cold applications. We diagnosed compression of brain probably due to blood-clot on motor tract for arm on brain cortex, since the paralytic symptoms were gradually developed. The above plan of treatment was continued until seventh day, when his symptoms became more profound and he had a rise of temperature. The clot neither showed any signs of absorption nor indicated any tendency to become organized, and we realized that the immediate dangers were from inflammation of brain substance and abscess and the probability of clot increasing its area of compression. And the remote dangers to be considered were from insanity, epilepsy, and atrophy of muscles of left arm. The indication for operative interference being clear, we advised trephining, which was done on the seventh day of injury. The scalp was shaved clean and washed; the fissure of Rolando was indicated by Champonnierre's line. We drew a horizontal line backward from posterior border of malar process of frontal bone on a level with upper and outer angle of orbit. A perpendicular line 1 1-5 inches long was drawn at a point on the horizontal line 2 4-5 inches from posterior border of malar process of frontal bone. These lines were marked with pen and ink and gave us a point C on the scalp. Another point D in the median line was obtained by measuring ¾ inch posterior to middle point between root of nose and lower edge of occipital protuberance. These two points C and D were connected with a straight line, which indicated the fissure of Rolando; a point opposite and anterior to median point of this line indicated the middle third of ascending frontal convolution, and this point was about one inch external to the scalp wound.

The course of white motor fibers in the brain is interesting. The motor fibers for the arm arise from ganglionic cells in the middle third of the ascending frontal convolution on both sides of fissure of Rolando and pass downward (joining white motor fibers for the leg coming from summit of ascending parietal convolution; joining those for the face from lower third of ascending and foot of second frontal convolutions, and joining those from Broca's speech center in foot of third and lower third of ascending frontal convolutions), converging and occupying bend of internal capsule; then passing into crus cerebri occupying its basal middle two-fifths, and then into pons Varolii, the fibers becoming divided and again converging into the medulla. Most of the fibers decussate here and pass down in lateral tracts of spinal cord (the remaining fibers pass down in anterior columns), and then out by anterior roots of spinal nerves, to be distributed to the arm through the brachial plexus.

The scalp was cleaned and the rules of antisepsis and asepsis were rigidly observed. Ether having been administered and a rubber tube passed around the scalp to prevent hemorrhage, a crucial incision, the cross being over the point selected, was made down to the bone, and a fissured fracture was now observed running the entire length of incision almost parallel to the sagittal suture, and there was no depression of bone. The line of fracture passed through the point selected for trephining, and a seven-eighths-inch trephine was set a little in front so that its circumference passed through the fissure. At every few turns of trephine the track was irrigated with a 1:4,000 bichloride solution and carefully cleaned. When the disk of bone was removed, a black clot was seen at the bottom between dura mater and skull and was irrigated with warm boiled water. The clot occupied about three-quarters of area of trephine, extending backward and inward, and was removed by forceps and irrigation. If we had used point first selected we would have come upon the clot centrally. The clot was about one-third inch thick and oblong in shape, its area equaling that of a silver dollar. The edges of bone were made smooth and hemorrhage checked by hot boiled water in twenty minutes. The finger was passed under the skull, but no spiculæ of bone could be found, and it was not deemed necessary to open dura mater. The wound was closed with catgut and dressed antiseptically. After the operation the patient was put to bed and given hypodermically morphine ⅛ grain, and atropia $\frac{1}{100}$ grain, from which he rested well that night. A saline purge was given next day and morphine again

on second night; after that bromide was sufficient to secure rest. Head was kept elevated, a light diet allowed, and on second day he was permitted to sit up some. Slight motion in arm returned before end of twenty-four hours and was confined to flexion and extension at elbow and shoulder joints, which proved that pressure had been removed. He now complained of no headache and felt well every way. The highest temperature was 101 3-5°, and pulse 90 on evening of third day, but soon returned to normal.

On January 3d, that is, the fourteenth day since the operation, I noticed a protruding mass pushing apart the edges of the wound while dressing, and readily recognized it to be fungus cerebri, or hernia of the brain. It probably had existed four or five days previous, during which time I had not seen it, as I had intrusted the dressing of the wound to the nurse, who allowed the bandages to become very loose. The patient had walked out of the house and overloaded his stomach, which caused vomiting, but the effect soon passed off. Compression was applied by means of roller bandages and sponges, and the mass was reduced somewhat, but by the twenty-eighth day it began to increase in size again and there were symptoms of brain irritation; headache, frequent and slow pulse, and temperature normal. I cauterized the fungus repeatedly with lunar caustic, but with little effect. The movements of left leg now became impaired, but he could walk alone. On the forty-second day a pocket of pus formed just behind the fungus under the scalp, but was opened and the symptoms improved. But on the forty-seventh day his symptoms again became worse, and he had vomiting and intense headache, pulse small and feeble, and temperature 101.1° F., but his mental faculties were clear. These symptoms continued, and on the fifty-third day there was escape of cerebro-spinal fluid. His mind now became blurred and he was delirious at times, with occasional vomiting, pupils dilated and fungus was now the size of a hen's egg, but somewhat flattened. Paralysis in both arm and leg was now complete. He became unconscious and passed into a coma three days before his death, which occurred on the sixty-fifth day after the operation. An autopsy was refused.

We frequently have such cases of head injury, although the symptoms of all are probably not so well defined. They are apparently not of very serious moment, but after a number of days develop meningitis or abscess, or else are followed later by epilepsy and insanity or permanent paralysis. In this case trephining was positively indicated, although it was followed by fungus cerebri. This complication usually is not to be expected with proper precautionary measures, and the probability of its occurrence does not materially enter into consideration in deciding upon the operation. A peculiarity of this case is the occurrence of this complication where there was a small trephine wound and no apparent injury to the dura mater. The treatment of fungus cerebri is unsatisfactory and most text-books speak of it evasively. As to the treatment of my case, I did not attempt anything radical on account of its medico-legal aspect.

Trephining under the rules of antisepsis and asepsis is not dangerous. Cases nearly always get well where there is no serious brain lesion, and even in extensive brain injury it does not materially add to the danger of the injury. Many cases of head injury are followed by epilepsy and insanity or permanent paralysis that could be prevented by the trephine. I have a case under observation now that I treated five years ago for head injury that was followed by irritative symptoms and three years later developed epileptic convulsions of an obstinate character. The operation would evidently have prevented this.

The practical deductions to be made from this case are:

1. That this patient would almost certainly have died in the first instance had not the clot been removed.

2. That there was a positive indication for trephining.

3. That it furnished a striking example of the practical value of the applied rules of topographical anatomy of the brain.

4. That the prevention of fungus cerebri is more important than the cure, and with proper precaution it is not to be looked for.

5. That the occurrence of fungus cerebriis very unusual in such a small trephine wound without injury to the dura-mater.

A NEW QUESTION IN MEDICAL JURISPRUDENCE—AN ILLUSTRATIVE CASE—MEDICAL EXPERT TESTIMONY—LAWYER'S BROW-BEATING.

JOHN M. CURRIER, M.D., Newport, Vt.

On the 24th day of November, 1893, Isaac Miles, of Greensboro Bend, Vt., disappeared and was never again seen alive. He was last seen in company with James Bow, night watchman at the steam sawmill, and Abner G. Cram, who was hanging around the engine-room of the mill. On April 24, 1894, the body of Miles was found under a pile of boards near the mill, with his skull extensively fractured; one of his malar bones was also fractured. The brain was softened so that a part of it ran out as the head was turned to one side. An autopsy of the body was made by the local physicians under the direction of the Board of Civil Authority. Suspicion at once rested upon Cram and Bow, and they were accordingly arrested upon the charge of murder, had a preliminary hearing before a justice of the peace and were lodged in jail to await trial at the September term of the county court. Cram was found guilty of manslaughter and Bow was set free.

At the trial the defense raised the question: Could the freezing of the brain during the winter cause expansion enough to fracture the skull? Expert testimony was introduced with the view to establish this point sufficiently to throw a doubt in the minds of the jurors. The State, anticipating that this question would be raised, had several physicians summoned to testify against it. In the defense it was claimed that the head was driven into the ground sufficiently far so that the expanding earth would fracture the skull and malar bone by force from without inward. This was a point well enough for the defense to make for the purpose of befogging a jury, but not very logical. If the brain would expand in freezing sufficiently to fracture the skull, the force from within outward would be counterbalanced by the freezing earth from without inward. None of the physicians who testified had ever seen a case of freezing of the brain or ever made an autopsy of one that had been frozen; consequently they could not testify from experience. The usual cross-questioning by the opposing counsel was made with the view solely of making the expert witnesses appear as ignorant and inefficient as possible, instead of eliciting the truth. One question that was asked by the counsel for the State of the medical witness called by the defense that should have been ruled out as an insult was: If a man's head was cut off, would he die? Such questions do no honor to the legal profession and their answers do not detract from the dignity of the medical profession. They must appear to the jurymen as trifling.

Will the brain of man or any animal expand enough from freezing to fracture the skull or cause a separation of the sutures? If a person freezes to death, the external parts of the body are the first to freeze, the internal parts are the last. If there should be a tendency for the brain to expand, the pressure would be from without toward the center and cause the blood to be driven down through the veins into the body; but if the person or animal dies before freezing, then there would be a greater tendency for the brain to expand, because the brain would be filled with blood, but not enough to produce a fracture of the skull. The cavity of the skull in life is a shut sac, and it is impossible to pump the blood out of it without supplying its place with some other liquid.

I have seen the skulls of animals that died in the winter months and were thrown out and exposed to very low temperatures, but none of them was ever fractured by the expansion of the brain.

I will relate one case that came under my observation in the town of Bath, N. H., in February, 1855, that comes directly to the point in this case. I was stopping with my brother one very cold day, when between two and three o'clock in the afternoon a drunken tramp by the name of "Bart" Somers called with a jug of rum. He took another "swig" from the jug and left the house before three o'clock; he went about eighty rods, sat down by the side of the road, took another "swig," according to indications, leaned over and took his "last sleep." The body was not found till the next

day at eleven o'clock in the forenoon. It was frozen so stiff that none of the limbs could be flexed or extended. The thermometer registered not less than 28° below zero during the whole night. The body was thus exposed to that low temperature about twenty hours. An inquest was held by the authorities and a thorough examination of the body was made. There was no fracture of the skull nor separation of the sutures to be found. This case proves conclusively that the freezing of the brain cannot produce a fracture of the skull.

COMMUNICATIONS.

THREE CASES OF ABDOMINAL SECTION FOR TRAUMATISM.

ROBERT G. LE CONTE, M.D., PHILADELPHIA.

These three cases occurred at the Pennsylvania Hospital. The first, C. I., an Italian laborer, aged thirty-five, was brought in by the patrol at 7:30 P.M., August 2, 1893, in a condition of profound shock. He had received four wounds from a thirty-eight-caliber revolver. The first had penetrated the abdomen in the left lumbar region, on a line with the umbilicus; as he turned to run away he received a second in the left side, between the twelfth rib and the crest of the ilium; the third penetrated the back in the left lumbar region, and the fourth passed through the right arm at the upper third. Hypodermics of strychnine and digitalis were given with external heat, etc. When his temperature began to rise he was immediately placed under ether. The abdomen was opened in the median line, and the cavity was found full of blood. Fifteen perforating wounds of the intestine were brought together with fine silk by means of the Lembert suture, and four wounds of the mesentery, in which the bowel was not involved, were stitched together, besides a few nicks in the bowel which had not penetrated to the mucous coat. A hasty examination of the spleen, stomach and liver was made, and as far as I could tell they had not been wounded. As the urine came clear from the catheter it was inferred that the kidneys had not been touched. The abdominal cavity was then flushed out with warm distilled water that had previously been boiled until the fluid ran clear, a glass drain inserted, and the abdomen closed with silkworm-gut sutures, the fascia being brought together with a continuous catgut suture. During the etherization the patient's condition was very bad. and hypodermics of strychnine and digitalis had to be repeatedly given. The operation lasted not quite two hours. At the conclusion his temperature was 97 ° and the pulse was almost imperceptible. The treatment consisted of strychnine, brandy and digitalis by hypodermic, and nothing was given by the mouth. At 3 A.M. the temperature had risen to 101°; pulse 96 and weak; respiration 30. He was delirious and very restless, and he had to be strapped and morphine given. At 10 A.M. his condition had improved. Temperature had fallen to 99°; pulse 110 and stronger; respiration 24, and he was quiet and his mind was clear. During the night the glass drain had been sucked dry every ten or fifteen minutes with a syringe, and the quantity of blood or bloody serum withdrawn amounted to about an ounce an hour. This gradually diminished to half an ounce by morning; urine was passed free from blood.

At 4 P.M. his temperature was 98⅘°, pulse 114 and respiration 22. The abdomen was moderately distended, and there was frequent belching of wind, but no vomiting. No flatus had been passed. Toward evening the temperature began to rise, the pulse became weaker, delirium set in and the patient slowly grew worse until death intervened the next day at noon, thirty-seven hours after operation. The post-mortem examination was made by the coroner's physician, and as I was not present I only have the few notes made by him. Two of the bullets were recovered;

one had entered the liver from behind, passed through it and lodged in one of the short ribs on the right side; the other was found just under the omentum near the stomach. None of the stitches in the intestines had given way and no extra perforations of the bowels were found.

Both of the other cases occurred in colored men, stevedores by occupation, strong and beautifully muscled specimens of manhood. They were admitted on the evening of the 10th of last February. The younger, Alex C., aged twenty-three, was stabbed in the abdomen a little below the umbilicus and about three inches to the right of the median line. The wound was a little over an inch long on the skin surface, and a small piece of omentum was protruding from it. There was very slight shock. The patient was immediately etherized, the abdomen opened in the median line, the omentum withdrawn through the median incision, the protruding portion ligated and cut off. The small intestine and cæcum with part of the ascending colon were next examined and no wounds found. The stab-wound was closed with two silkworm-gut stitches, the peritoneum washed out with warm boiled distilled water, and the abdomen closed without drainage with silkworm-gut sutures, the fascia being brought together with a continuous catgut suture. The next day his temperature rose to 100° and then fell to normal, and he made an uninterrupted recovery. The stitches were removed on the ninth day and the wound was entirely healed.

The elder, Frank W., aged forty, also had a stab-wound in the right upper hypogastric region, about two inches from the median line. He had had free hemorrhage from the wound, as his clothes were partly saturated with blood. The cut on the surface was a little less than an inch long, and after enlarging it slightly my finger readily passed into the abdominal cavity. There was but little shock. The patient was etherized and the abdomen opened in the median line. A quantity of arterial blood immediately presented. The bowel and the omentum were carefully examined and no wounds found. It was then concluded that the deep epigastric artery had been severed, and as I did not think it desirable to enlarge the stab-wound, two deep sutures were passed on either side of it, through the peritoneum, and tied. The stab-wound was then closed with silkworm-gut, the peritoneum washed out, and the abdomen closed in the same manner as in the previous case. As I was not absolutely confident that I had checked all the hemorrhage, and thought it possible I might have overlooked some bleeding point, a glass drain was left in. The tube discharged about f℥ss an hour of bloody serum during the night, and then gradually diminished in quantity. The next day his temperature went up to 101½° for a few hours, but soon fell to normal again. On the 17th, seven days after operation, he developed a mild delirium which was thought to be alcoholic, and he was placed on the ward delirium tremens mixture. This subsided by the 23d. On March 3d he was allowed to get up, the wound being healed, except for a small superficial ulceration, the remains of the tract formed by the tube.

I should like to present the following points for consideration this evening:

1. That the surgeon must assure himself absolutely that the peritoneal cavity has been opened before proceding to operate, either by means of the finger or probe, or the protrusion of some of the abdominal viscera or contents of the viscera. If the wound is so small that this cannot be demonstrated, it must be enlarged with the knife, until it is proved either to have penetrated or not to have penetrated.

2. That as speed is such an important factor in these cases, and that the patient's chances of recovery often diminish proportionately with the length of the operation, I would advocate the median incision in all cases except where the liver has been manifestly injured, because the abdominal cavity can be opened more quickly and more bloodlessly in the median line, and a more thorough search of all the organs can be made in a much shorter time than from any other incision, and also because the wound can be more quickly closed and with less danger of a future hernia resulting.

3. The abdomen having been opened and a number of wounds of the intestines found, I would advise that two surgeons should work at the same time, sewing up these perforations, using the continuous or running Lembert suture as a means of saving time, the rest of the intestines be-

ing covered with hot cloths to prevent shock. Fine twisted silk is the best suture for this purpose, and the needle must be smooth and round, without sharp edges.

4. I would recommend the flushing out the peritoneal cavity with a warm solution as a means of cleansing it from clots, blood, etc., as a means of reducing shock, and also because it allows the intestines to float and to resume as nearly as possible their normal position in the abdominal cavity. This solution should be warm water that had previously been sterilized by boiling, containing seven-tenths of 1 per cent. of salt, as the blood, when freed from its solid constituent, represents most nearly a seven-tenth of 1 per cent. salt solution both in its reaction and specific gravity. It is a well-known fact that two fluids of different density and reaction, when separated by a thin animal membrane, will mingle by osmosis, and that pure water will in such cases abstract the salts from the blood, causing a primary blanching of the membrane, soon followed by a secondary hyperæmia, with injection of its vessels. If the eye be washed with pure water, an injection of the vessels of the conjunctiva will follow, but if a little salt is added to the water, no injection will result. It is easy to conceive that the action of pure water on the conjunctiva would also follow in the case of the peritoneum, and experiments on animals have proved this to be a fact.

5. Unless the operator is certain that he has checked all hemorrhage and that there is nothing more than a slight oozing present, I would recommend the use of a glass drain, believing that the dangers of infection through the tube are much less than from a small collection of bloody serum, a most acceptable medium for any septic material which may not have been removed by the flushing out of the cavity. The drain should not remain in more than thirty-six or forty-eight hours, as in that time lymph has been thrown out from the adjacent peritoneum, gluing the tissues together, so that a perfect tube-tract has been formed, after which the tube is more dangerous than advantageous.

6. That the incision should be closed by passing a set of silkworm-gut sutures entirely through the abdominal wall, from skin to peritoneum, and, before these are tied, stitching together the fascia with a continuous catgut suture. As the fascia is by far the most important structure in the support of the abdominal contents, it is necessary that its edges should be neatly and closely approximated, and for this purpose a moderately thick catgut suture, which is allowed to remain buried in the tissue, gives the best results. The stitches through the abdominal wall will bring the peritoneum together just as well when it is separately sewed, and saves the time that this extra row of sutures would require. For this purpose silkworm-gut is preferable to silk, as it is not irritating and non-absorbent, while silk acts like a drain, carrying the discharges through the whole course of the wound. If these discharges at any time become septic a stitch-abscess results. The stitches should remain in eight or nine days, after which the wound is supported by adhesive straps, and when the patient is allowed to get up, not before the twenty-first day, an abdominal supporter should be worn for several months. If the patient is much beyond middle life the supporter may have to be worn for years.

Lastly, the after-treatment of the patient. As the wounding of the bowel and the necessary handling of that viscus in sewing up the wound and examining it for further perforations causes paralysis of the gut, with its concomitant distention from gases, the after-treatment should be directed toward the relief of this distention and the overcoming of the paralysis, as to my mind there is far more danger of the sutures giving way from this over-distention than there is from any peristaltic action that can be induced. Secondly, paralysis of the gut favors ptomaine absorption, and the sooner this paralysis is overcome and the poisonous substances swept out of the alimentary tract, the greater are the patient's chances of recovery.

I would therefore advocate the use of salts, because they excite peristalsis, relieve the distention, and sweep the ptomaines out of the alimentary tract, besides drying the peritoneal cavity, and thus removing a possible source of septic infection. I believe the exhibition of opium to be strongly contraindicated, as it increases the paralysis of the bowel, allows the tension on the stitches to become very great from over-distention, and favors the absorption of ptomaines. Of

course, there are a certain number of cases where restlessness is marked, and where the dangers of its exhausting the patient are so prominent as to make it the cardinal symptom to combat. In these cases morphine must be given by the hypodermic until quiet is obtained.

To sum up, my treatment would be as follows: Strychnine, brandy and digitalis by the hypodermic, water containing a little salt by the rectum, to quench thirst. Six hours after the operation one-half-grain doses of calomel by the mouth for six consecutive hours, and then drachm-doses of Epsom salts every hour, given in as concentrated a form as possible, until the bowels are moved. No food until the functions of the bowels are well established, and then milk only in small quantities often repeated. I have seen the bowel twice ruptured in the removal of abdominal tumors, owing to its strong adhesion to the growth. In each case it was promptly sewed up, and the removal of the growth proceeded with. The patients were placed on the usual treatment of calomel, followed by salts, and each made an uninterrupted recovery. On talking this over afterward with the operator, he stated that when the adhesions were so strong that it became a question of rupturing the bowel or not removing the tumor, he always chose to rupture the gut, as he had never had any bad results follow, or seen a single symptom which could be attributed to this rupture.

In conclusion, I believe that the three great causes of death in these cases are shock, ptomaine absorption and peritonitis, in the order named, and that the treatment should be successively directed against them.

CASE OF GUNSHOT WOUND OF ABDOMEN AND LUNG.

LEWIS W. STEINBACH, M.D., PHILADELPHIA.

A. H., aged thirty-six years, white, a Philadelphia police sergeant, was admitted to the Polyclinic Hospital August 30, 1894. Twenty minutes previous to admission he had been accidentally shot in the abdomen by a 44-caliber pistol.

His temperature on admission was 98°, pulse 60, respiration 28. He was weak and faint, although externally he had not lost much blood. With the assistance of two officers he had walked from the place of shooting to the hospital, comprising several blocks.

Patient complained of some pain around umbilicus, and was unable to void his urine.

The history obtained from the patient states that he was sitting in a chair, while the person who shot him was standing to his right, the pistol pointing slightly to patient's left. On examining the abdomen a small wound one-quarter inch in diameter was seen two inches below and to the right of the umbilicus.

After cleansing the part a probe was gently inserted into the wound, and it was probed in all directions. The muscles had been torn up in several directions, so that this was not satisfactory, although there seemed to be a track in an upward direction and to the left, which from the history seemed to be the true course which the ball had taken. A small quantity of sterile water was then injected into the wound; but, as it returned, it could not be made out that the abdominal cavity had been entered, although this was what was thought to be the case.

Upon consultation with three of the hospital surgeons it was decided to etherize the patient, follow the upward track, and if the abdominal cavity had been entered, to do a cœliotomy in order to ascertain the extent of injury.

Patient was etherized, and after all antiseptic precautions had been taken, a grooved director was introduced into the wound, and after some little trouble, as the track was irregular, it was laid open to about an inch in extent. Upon pushing the director further it entered the peritoneal cavity. The consensus of opinion was to do a laparotomy. A three-inch incision was made in the median line, and upon opening the peritoneal cavity a considerable quantity of blood escaped through the wound. The intestine was carefully examined, and nine perforations made by the bullet were found. These were principally in the lower part of the jejunum and the

ileum. One was wholly in the mesentery, while the others chiefly lay at junction of it with intestine; and it was from these that the greater part of the blood was oozing. The colon was not perforated.

The various perforations were sutured with Lembert suture, silk being used. After carefully going over the small intestine they were replaced, and the abdominal cavity thoroughly washed with warm sterile water until all blood and clots were removed and the fluid returned clear. A glass drainage-tube was placed in the lower part of the wound, and silkworm-gut sutures introduced, closing the incision. The ordinary antiseptic dressing was applied.

The bullet had not been found, but was thought to have taken an upward course to the right of the spinal column.

The operation was a long one, and it was found necessary to administer strychnia and atropia to combat the shock. Temperature after operation was 99.8°; pulse, 120; respiration, 28.

The patient came out of the ether and seemed to rally; but during the evening his pulse became weak, thready, and very rapid, reaching 156 by 9 P.M. The temperature kept rising slowly and steadily until 3 A.M. it reached 102.4°. About ℥iv. fluid blood and serum was obtained through the drainage-tube. It did not clear, though it lessened in quantity toward morning. It was also noticed that the patient coughed up a small quantity of a dark chocolate-colored fluid. Stimulating treatment was kept up during the night. He complained greatly of thirst, was extremely restless, it being with difficulty he was restrained in bed. But at no time did he complain of pain.

The pulse became weaker and weaker, and at 8:36 o'clock the morning following operation he died. Temperature taken half an hour previous to death registered 105.6°.

An autopsy was held by the coroner, and it was found that the bullet had pursued an upward course after striking the spinal column, passing beneath the diaphragm, rupturing some of the vessels at the root of the right lung, which was engorged with blood. The right pleura was filled with blood. There was also blood in the abdominal cavity, due to rupture of small vessels in liver tissue. The intestines looked ecchymotic in places; but the places that had been sutured showed commencing union. The bullet was not found, but traced to muscles of the back.

CASE OF GUNSHOT WOUND OF LIVER AND LUNG.

THOMAS S. K. MORTON, M.D.,* PHILADELPHIA.

A boy, aged nine and a half years, was admitted to the Pennsylvania Hospital, September 11, 1894, with a history that he had been shot by a 32-caliber revolver at short range but a few moments previously. I saw him almost at once after admission, and found a bullet wound one and a half inches below and half an inch to the left of the ensiform cartilage. He was not especially shocked. Was said to have vomited considerable blood, and complained of great pain in the epigastrium. Abdomen not distended.

Ether was administered and perforation of the abdominal cavity proved by enlarging the bullett wound slightly and passing a probe. Having thus made certain that the peritoneum had been entered, an incision was made in the median line from the ensiform catilage downward for four inches. Upon laying open the peritoneum much fluid blood and some large clots flowed out. It was found that the ball had passed through the right lobe of the liver, two and a half inches behind the anterior margin, then emerged just above the gastro-hepatic omentum, had almost totally destroyed the lobus Spigelii, then had torn a large hole in the lesser omentum, again perforated the peritoneum, struck the first lumbar vertebra, and became lost. Blood welled up in large quantities from the posterior peritoneal opening, mostly venous, but partially arterial. A finger-tip only could be passed into this wound. There was no wound of stomach or intestines. The wound of the right lobe, as well as that of the Spigelian lobe of the liver, was not bleeding. A column of iodoform gauze was carried

* Professor of Surgery in the Philadelphia Polyclinic.

down so as to block the wounds of the lesser omentum and posterior layer of the peritoneum, and at the same time to press upon the mutilated Spigelian lobe and posterior or exit wound of the right lobe of the liver. The packing was continued and brought out through the parietal wound. The wound of entrance into the right lobe was not interfered with. The abdominal wound was now closed around the gauze drain after copious irrigation of the surroundings with hot salt solution. As it was suspected that much blood had gravitated into the pelvic and lower portions of the abdomen, which could not readily be washed out by irrigation from above, it was determined to make a small opening above the pubis for that purpose and to put in a drain-tube. Accordingly a half-inch incision was made just above the symphysis, and much fluid blood and clots were washed out through it by means of a long irrigator tube. A glass drain was carried through this wound down to the bottom of the pelvis, to serve as an index should further hemorrhage take place into the abdomen. But despite all efforts the lad died in a few hours. At the post-mortem examination it was discovered that the ball had passed between the aorta and vena cava, and perforated the right crus of the diaphragm before striking the first lumbar vertebra. In the latter it cut a large groove, and was deflected upward and outward through the pleura and into the substance of the right lung, where it was found imbedded. The lower lobes of this lung were distended by blood, and over a quart in addition filled the pleural sac. No wounds of other viscera were discovered. There was no blood in the abdominal cavity.

Upon careful inquiry after death I ascertained that the reported vomiting of blood had been incorrect; that in reality he had coughed up and not vomited it. No especial examination of the chest was made before operation, and no signs appeared to call attention to that locality. But the bleeding therein was unquestionably the immediate cause of death. Had the ball not wounded the lung I believe the boy would have had a good chance of recovery afforded him by the operation.

TRANSLATIONS.

PATHOLOGIC ANATOMY AND PHYSIOLOGY OF GENERAL PARALYSIS.*

Joffroy (*Le Bulletin Médicale*, June 13, 1894) has presented a recapitulation of the microscopic lesions and of the pathologic physiology of general paralysis. In the one the origin of the disease is stated to be a sclerous encephalitis, the lesions of the vessels and of the interstitial tissue being primordial; the other theory, on the contrary, considers the beginning of the histologic process as residing in an alteration of the gray elements of the brain, the cells and nerve tubes, and the interstitial lesions as secondary, following at a period more or less late.

The microscopic lesions of the disease are as follows. The alterations in the vessels, it is necessary to recognize, hold the first place because of their intensity. There is an accumulation of nuclei around their walls; there also exists a state of repletion of all of the vessels—the arteries, the capillaries and the veins are distended and gorged with blood. In fact, the vessels appear to be more numerous than in the normal state, but Joffroy doubts whether there be an actual multiplication; he attributes their appearance of increase in number to an atrophy of the nervous substance. The volume of the brain being diminished the vessels approach one another, and this results in a change of aspect which may cause an appearance of multiplication. All the writers have noted the multiplication of nodules in the vascular walls. This lesion is not absolutely constant and is ordinarily more marked when the disease is of ancient date. If, on the contrary, the duration has been short, generally very few of the proliferated nodules are to be found. In the old individuals there may also be noted a granulo-fatty degeneration of the small vessels which results from an alteration in their external tunic and especially in their middle

* Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Dorland, M.D.

coat. Mendel, according to whom the cortical vessels play an important *rôle*, has descried in the altered vessels miliary aneurisms, ampullary dilatation. A lesion of great importance consists in an extravasation of leucocytes into the adventitious sheath of the vessels. This diapedesis is constant; it is found in every autopsy of general paralysis, whatever may be the age or form of the disease, whether of long or short duration.

The extravasated leucocytes are normal or granular. At times the lymph spaces are filled not only with white globules, but also with a certain number of red corpuscles. In certain cases may also be seen the gelatinous corpuscles to which Dagonet has recently called attention. These are hyaline balls, grouped in a circle, disposed in rosettes and composed of altered nervous substance. The diapedesis is a fundamental lesion as much from its constancy as from its intensity and its signification. When the disease has been of long duration in certain cases may be noted a thickening of the walls of the vessels, with a modification of appearance which has been described under the name of vitreous degeneration by Meyer, hyaline degeneration by Fischl, Thomas and Holschewnikoff, amyloid degeneration by Tigges, colloid degeneration by Magnan, and waxy degeneration by Lubimoff.

These different forms of degeneration appear when there has been a rapid absorption of the nervous substance, and have also been frequently noted in syringomyelia. The lymph spaces, both perivascular and pericellular, are dilated. The neuroglia presents some important modifications. The most important of these is an increase of its substance in every portion of the brain, as demonstrated by Magnan. The neuroglic cells are increased in volume, some attaining enormous dimensions; they present numerous and larger prolongations and appear to be increased in number; this, however, is due to an atrophy of the nerve tissue between them. Nevertheless a true karyokinesis exists in the proliferated nodules.

Alterations in the Nervous Elements Themselves.—These are constant in the course of general paralysis. In 1884 Tuczek demonstrated the disappearance of the intracortical, transverse, tangential and subcortical fibers of the myelin. This lesion is manifest and may be noted throughout the entire convolutions. It has also been noted in the optic thalami, as has been shown by Lissauer and Zagari, in the geniculate ganglia, the quadrigeminal bodies and in the cerebellum. It is especially in the cortical substance, however, that the disappearance of the tubes is to be noted. Certain authors have noted that this lesion of Tuczek is not restricted exclusively to general paralysis; it is also found in senile dementia and in the neighborhood of cerebral tumors. The lesions of the nervous cellules have been carefully described by Meschede. The lesions of the neuroglic tissue and of the vessels are generally predominant; in certain cases the cerebral cellules are diminished in number and at times exceedingly atrophied. In 1891, in the Congress of Mental Medicine, Joffroy substained the opinion that general paralysis was a parenchymatous encephalitis, and this view has been taken also by Professor Pierret. He considers that the primary cause of the disease resides in heredity or predisposition, while alcoholic, saturnine, syphilitic and puerperal poisonings merely act as accessory causes.

Bone-Marrow in Anæmia.

Dr. Dixon recommends bone-marrow extract in the treatment of anæmia. The red marrow of bone being probably the chief agent in promoting the development of red-blood corpuscles, it seemed feasible to suppose that an extract of this substance, if introduced into the anæmic human organism, might act as a stimulant to the formative process and increase the rate of production of the red corpuscles. As the tissue-forming power in young animals is more active than in older animals, the bones of the former are preferable as a source of marrow extract. (To prepare the extract the heads of the long bones obtained from recently killed animals are broken into pieces and digested in glycerine, with frequent agitation. When the extraction is complete, after several days the extract is filtered off and is ready for use. It is red or reddish-brown in color and is devoid of any unpleasant taste or odor.) It may be given in teaspoonful doses once or twice a day, either out of the spoon or spread between thin pieces of bread. In several cases of pronounced anæmia a marvelous improvement, coincident with an increase of red corpuscles, has been observed under this treatment.

HAROLD H. KYNETT, A.M., M.D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, NOVEMBER 24, 1894.

EDITORIAL.

MALPRACTICE.

With profit the motto of the great lawyer, David Paul Brown, could be adopted by the medical and surgical profession: "A doctor who knows nothing of law, and a lawyer who knows nothing of medicine, are deficient in essential requisites of their respective professions."

Medical men and surgeons are vitally interested in whatever relates to their liabilities as practitioners. The busy practitioner—and he is generally busy in proportion to his zeal, ability and competency for his work—has little time to devote to the long-drawn-out and very generally confused treatise on medico-legal questions contained in books. The gist of what he wants, what he needs, is, what are his duties and liabilities, where do they begin and where end, what constitutes legal rights, wrongs and remedies as they relate to his profession. It has been too frequent, and yet is, that criminal or civil responsibility for omission or commission has been charged to innocent practitioners.

In a not very distant past so great were the facilities, so strong the encouragement of lawyers who shared in the spoils, to bring suits for malpractice, that able surgeons would not risk this constant menace by the practice of surgery. They would practice medicine but not surgery, for the reason of the dangers attending its practice. They turned in alarm from the risks of having the accumulations of years of labor wrested from them by ruinous litigation. These suits were more frequent in the past than now. A just and enlightened judiciary and a united profession has largely diminished the number of these cases, instituted, as they about always are, from avarice, malice or ignorance.

There are, however, many prosecutions instituted that never find their way into legal reports: they are only locally heard of through newspapers of narrow neighborhood circulation, and only serve to startle practitioners of a limited section with the perils of medical and surgical practice. The charges of learned judges and the decisions of the higher courts have laid

down the underlying principles of these cases with such clearness and emphasis as to do more than merely discourage their institution, even to condemn them in many instances as vexatious and cruelly unjust. The number of these cases will continue to decrease with the advance of medico-legal knowledge in the professions of both law and medicine, and with the maintenance of a high standard of anatomical, physiological and pathological knowledge in the latter profession.

Of the many embarrassments which the physician has to confront in general practice, there is none greater or that so severely tests professional merit and character, that so endangers reputation and to which he is so averse, as being called into the courts, whether of criminal or civil law.

There is one fact of easy recognition. That is, that more is expected of physicians—that they are more subjected to indiscriminate, ill-considered and unsparing criticism than any other class of men. When errors or mistakes are made they are noised abroad, passed from neighbor to neighbor, from one acquaintance to another, and not infrequently heralded through the newspapers. The attempt is often to hold them legally liable for what no human skill could avoid or human foresight anticipate. Nothing is allowed for the complex character of the trouble with which they have to deal, the hidden influences which baffle the best science.

Latent conditions often give the most skillful of surgeons bad results. For these he is sometimes carried into vexatious and expensive litigation through the counsel of some unscrupulous lawyer ignorant of the principles governing malpractice cases.

Medicine and surgery have emerged from many forms of barbarism and superstition, and so have the law courts from barbarous rulings and decisions in malpractice cases. The real, inherent difficulties of the profession have grown to be better understood by the law courts. It is recognized that there is very much to qualify results in any given case. An eminent authority condenses much truth in the following: "A source of uncertainty in the practical art of medicine is the difficulty we find in applying to new cases the knowledge we have acquired from observation. This application is made upon the principle of either experience or analogy.

"We are said to proceed upon experience when the circumstances in the new case are the same as in those cases from which our knowledge was derived. When the circumstances are not the same, but similar, we proceed upon analogy, and our confidence in the result is weaker than when we proceed on experience. The more numerous the points of resemblance are, the greater is our confidence, because it approaches the more nearly to that which we derive from experience; and the fewer the points of resemblance, the confidence we feel is more and more diminished. When in the practice of medicine we apply to new cases the knowledge acquired from others, which we believe to have been of the same nature, the difficulties are so great that it is doubtful whether in any case we can properly be said to act upon experience, as we do in other departments of science; for we have not the means of determining with certainty that the condition of the disease, the habits of the patient, and all the circumstances that enter into the character of the affection are precisely the same in the two cases; and if they differ in any one particular, we cannot be said to act from experience but from analogy. The difficulties and sources of uncertainties that meet us at every stage of such investigations are, in fact, so great and numerous that those who have had the most extensive opportunities of observation will be the first to acknowledge that our pre-

tended experience must, in general, sink into analogy, and even our analogy too often into conjecture."

As these difficulties and embarrassments grow to be better understood by courts and by jurymen who come from the body of our communities, the fewer will be malpractice suits, and the more frequent the verdict "not guilty."

The rigid enforcement of the old rule that the practitioner must apply, without mistake, what is settled in the profession, was, up to a very recent date, a fruitful source of suits for malpractice. This rule has been greatly modified under the light of the best modern judicial authorities. Progress in modern medicine and surgery has pushed aside many old practices as useless and in many instances injurious. Especially is there allowed greater room for difference of opinion in the exercise of the art of surgery, for there are usually several ways for doing the same thing, different operations for the same injuries, each operator having a partiality for his own methods, those by which he has secured the best results.

One of the best legal authorities on the law of malpractice very aptly says: "It is not enough for a surgeon to plead that his treatment was that taught him by the ablest members of the profession and the best schools twenty-five years ago, because in a science that is advancing with the rapidity of medicine and surgery—that is, by observation and experience, yearly, and almost daily, correcting errors in practice and abandoning hoary-headed theories, the fallacy of which has become apparent, upon which the practice has heretofore been based—that is receiving auxiliary agencies from all the rapidly advancing sister sciences—there will be new facilities afforded in practice year by year and errors constantly exploded. The authority, therefore, that was at a previous day considered good, and upon which the courts acted, may not at this time be admitted as the present standard of knowledge required of the physician and surgeon. Old physicians and surgeons cannot, therefore, rely with safety upon their elementary education and what they may have learned in practice. It is absolutely important for the protection of the patient as well as of the surgeon, if he assumes the responsibilty of performing an operation fraught with so great interest, that he should make use of every reasonable means of knowing what is considered the best treatment at the time of the operation—not what would have been the proper course twenty years ago. A medical man cannot, with any safety or propriety, practice year after year without keeping himself informed as to the improvements of his science, especially if he practice surgery."

The responsibilities and liabilities of the profession are not in any strict sense diminishing; they broaden with the light and advance of the profession. The law keeps pace in its requirements.

Responsibility is measured by the professed ability to accomplish. Where a large price is demanded and paid for services, there is a corresponding increase of responsibility, there being an implied claim of superiority of knowledge and skill over others. And this responsibility is only reduced or relieved by the operation of causes or influences beyond the physician's or surgeon's detection, or over which he has no control.

Penal laws are made to protect society against the charlatan and the ignorance of the quack. For an educated, reputable and honorable physician to compromise such cases is an implied consent to be classed with those professional pests; is to compromise personal honor and the honor of the profession. Our judicial tribunals will do no more than that which every educated and honorable physician and surgeon will demand, that the severest judgment of the law should be inflicted upon

those who ignorantly or recklessly trifle with health and human life.

Every detail of professional conduct, upon which is founded the good name and repute of the physician and surgeon, receives the severest of judicial scrutiny in all malpractice suits. And there is accountability in damages, measurable with the extent of the evil results, for ignorant, careless or unprofessional conduct. One of the ablest of English surgeons says: "Genius for our art may shine out on great occasions, and brilliant devices contend against remarkable deviations from health, but *conduct* is *required* of us all. The word *conduct* has a wide interpretation; it appeals to the application of the humanities of life, as well as the exercise of skill and industry in the application of our best resources in the treatment of disease."

The law regards the undertaking to be only for the use of proper means. It is not regarded that the cure is in the physician, but is largely dependent upon the constitution of the patient and the influences of causes beyond his control. In one of the oldest reported English cases (1767) the Lord Chief Justice said: "Ignorance is rashness. A physician may intend well and yet his conduct be so exceptional that he must be held liable criminally when life is lost by such conduct, though he did not intend it at the time."

Though extraordinary skill is not required when the act to be done depends on the skill of the operator alone, the law will imply an engagement to use that skill and to produce the desired result, from the employment of one professing it and holding himself out to the world as having it. The errors for which he may be held liable may be either of omission or commission. He is not responsible for those disasters which are not the result of his own conduct, or for those the result of the refractory conduct of the patient, upon whom rests the collateral duties of submitting to the requirements of his professional attendant.

He is liable for any unnecessary pain or delay occasioned by the application of unskillful and improper remedies. Amputations, fractures and dislocations, and deformities arising therefrom, are made the grounds of many malpractice suits.

In the cases of amputation a legal text writer puts the subject in strong form: Under this state of things one of the most difficult and close questions of surgery arises—a question upon the solution of which depends the life of the patient, perhaps, and possibly the reputation of the surgeon—to decide which question correctly calls into requisition correct logic, close observation and extensive surgical knowledge; and that is the question of *amputation*. In these difficult cases the result, let it be for or against amputation, will generally be critically questioned. The loss of a limb, on the one hand, will raise the question of the propriety of the amputation long after the real condition that was supposed to demand it is forgotten by all, perhaps, except the surgeon himself. If amputation is overruled and the patient dies, the surgeon is blamed for the sad result. These cases are fruitful sources of litigation. If the limb was amputated, it is said there was gross carelessness or recklessness and a want of care and skill—that the limb might have been saved had proper effort been made at the right time. If the surgeon gives to the patient the benefit of a doubt as to the propriety of amputation in a close case, and after long and vigilant watching surmounts great difficulties, saves the limb in a condition to be of great use to the patient, yet, it not being a perfect cure, then the surgeon is said still to be at fault, notwithstanding the injury was so severe that the question of amputation hung evenly in the balance for a time, and he is sued.

Such cases are familiar to the profession.

ABSTRACTS.

THE FATE OF THIERSCH SKIN GRAFTS.

Goldmann (*Beitrage zur klinischen Chirurgie*) says that when a wound has been successfully grafted after the manner of Thiersch, healing occurs without the formation of granulations and with scarcely any cicatricial contraction. After a few months the new skin is reddish and somewhat glistening; it is on the same level as the surrounding skin; it is more or less movable on its bed and frequently possesses both tactile and thermal sensibility. When the changes in the grafts are examined in detail, it is found that in the first instance there is some desquamation of the horny layer, while at the same time there is active proliferation in the middle layers of the epidermis; ultimately the epithelium as a whole is thin and the papillæ are of small size. An entirely new vascular network is formed beneath the epidermis which nourishes the latter and persists for years, which accounts for the redder tinge of the new epidermis and differentiates it from the surrounding skin. The grafted skin reaches the level of the surrounding skin surface more rapidly when the grafts are placed on a vascular bed; in the forehead this level has been attained in four to six weeks. It fails to attain this level when the grafts are placed on a granulating surface, as in the latter case there will be cicatricial tissue beneath the new skin. After an interval of months the mobility of the grafted skin is so developed that it can be lifted up in folds from the tissues beneath. Return of sensibility occurs sooner at the margins than at the center of the grafted area, and where large gaps have been filled up it may not return at all.

In discussing the anatomical basis of these clinical facts, the writer points out that the normal mobility of the skin on the subjacent tissues depends on the network of elastic fibers which connect the former with the latter. By adopting a special stain for the elastic fibers, he was able to prove that these were abundantly formed in the true skin beneath the grafts, and that they were prolonged right up to and into the papillæ, so as to end immediately beneath the epidermis. The presence of the new elastic fibers, derived from the mother skin, gives the grafted skin greater resisting power, so that it is able to withstand traction and pressure. Inasmuch as granulating and cicatricial processes hinder or prevent this growth of elastic fibers into the graft, we are able to understand why the results obtained are so much better when the grafts are placed on a recent wound than on one which is granulating. It is also to be noted that the development of the elastic network explains the absence of cicatricial shrinking of the transplanted skin. The new vessels which are formed from the mother tissue have a great influence in raising the grafted area to the level of the surrounding skin. In this they are assisted by the formation of elastic fibers and of young connective tissue. In a successful case there is no scar tissue to be seen. The return of sensibility to touch, pain and temperature is explained by the formation of new medullated nerve fibers, which are probably also derived from the mother tissue and which the author has traced into the grafted skin. This method of grafting succeeds at all ages to an equal degree.

Rational Treatment of Appendicitis.

Ashton (Denver *Medical Times*) holds that it is impossible, with our present means and methods of diagnosis, to know the nature of the pathological changes taking place during the course of an attack of appendicitis.

That all forms of appendicitis are dangerous to life, as it has been demonstrated that germs pass through the walls of the appendix without the presence of either ulceration or perforation.

That surgical interference is indicated in primary and secondary attacks of appendicitis so soon as the diagnosis is clear.

That surgical interference is not advised during an acute attack of appendicitis, except when grave symptoms intervene, unless a competent surgeon is at hand. Under these circumstances the case should be operated upon after the so-called recovery.

PATHOLOGICAL FICTION.

Among physicians "The Heavenly Twins" is looked upon not as a literary venture to be judged by artistic standards, but as a readable presentation of symptoms which suggest definite pathological condition.

"Ships That Pass in the Night" is admirable as a pulmonary record, and "The Yellow Aster" affords an insight into the psychic phenomena resulting from neglect of natural instincts and desires which, surviving the appropriate period of life, subsequently assert themselves in the form of belated maternal love and *ex post facto* philoprogenitiveness.

As to Miss Harraden's book, while we find it useful in the profession for its glimpses into refined sick-room conversation and pulmonary persiflage, we regret, from a medical point of view, that after giving such a careful history of the heroine's case, the author permitted her to be killed by an omnibus. It is humiliating, after following attentively the course of the disease and the method of treatment, to be told that an omnibus was the cause of death and to be dismissed without hearing the result of the autopsy. Moreover, we found her style so delightful that we would have gladly followed the hero to the last hemorrhage, but that, too, was denied us.

Sarah Grand's cases are open to the same objection of incompleteness. She starts out enticingly with such a character, for instance, as Edith's husband, but leaves the later and more interesting phases of his pathological history untold. As a general rule, however, she comes up to the requirement of modern fiction; the cases of most of her characters can be diagnosed; and with a little more clinical experience we have no doubt that her future novels will be above reproach.

There is danger lest in the first stages of the medical movement in literature young writers will attempt to cover too wide a pathological area in their novels and forget the inexorable law of specialism that obtains in the medical profession itself.

To introduce a paretic or ataxic patient in a dermatological novel would not only destroy the unity of the story, but would justly expose the author to a suspicion of a want of thoroughness. If the writer has determined upon appendicitis as his plot he should not waste his energies upon irrelevant diseases in his minor characters. He could gain variety by introducing other forms of enteric disorders, but should never exceed the limits of the abdominal region. Until he has had a thorough medical training, we think the course of a single disease should supply him with all the medico-literary material that he can handle in an intelligent manner. A blow on the head supplied the author of "God's Fool" with all the plot that he needed; Ibsen's "Ghosts" is simply the dramatization of an inherited brain disease, and many a successful short story is based upon a case of simple mania with delusions.—*Amer. Medico-Surg. Bull.*

Acute Lacunar Diphtheria.

Dr. Koplik, of New York (*N. Y. Med. Jour.*), proves that many cases of so-called "lacunar" or "follicular" tonsilitis are in reality diphtheria. He insists upon animal experiments as the only positive proof of the virulence of the Loeffler bacillus. He divides cases into three clinical groups: 1. The course is mild; patients showing little or no disturbance, appetite is good; they are up and about; throat symptoms are absent or only slight; examination shows a general hyperæmia and enlarged tonsils; no membrane is found, but only here and there a yellow spot showing the opening of a follicle; lymph nodes at right angle appear possibly enlarged. Next day the child is apparently as well as ever. Koplik demonstrates the utter fallacy of such assumption of recovery. These apparently harmless plugs are the focus of virulent bacilli, which have been extracted from the same sites up to even three weeks after the alleged recovery. 2. Here the symptoms are distinctly more severe than in group 1, both locally and constitutionally; the children are quite sick, and the general clinical course is like that of the "streptococcus" sore throats; a soft, yellowish fibrinous mass exudes from the lacunæ, though there is no true membrane on the tonsillar surface proper; nodes are enlarged. 3. The cases of the last group show a malignant course from the outset. The lacunar gives way to a more severe type into which the nasal mucous membrane may be drawn.

SOCIETY REPORTS.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of October 12, 1894.

Section on General Surgery.

Prof. William S. Forbes, by invitation, exhibited his improved lithotrite and demonstrated the method of testing and measuring the strength of lithotrites, as well as the measured crushing resistance of vesical calculi. He said:

Mr. President and Gentlemen: I appreciate the compliment the Executive Committee of this body has extended to me in inviting me to appear before you this evening and explain the new lithotrite which I placed before the American Surgical Association at Washington in June last. It may be well to commence by stating the origin of this lithotrite. I had five cases of stone in the bladder, which came to me in a group; there was a man of eighty years, a child of three, a boy of seventeen, and two adults between forty-five and fifty. After I had finished crushing the stones and the patients had returned to their homes, I thought of the large number of stones that were relegated to the knife—the large, hard stones—and it occurred to me to attempt to improve the strength of the lithotrite in order that its efficiency might be extended so as to embrace these large and hard stones. This consumed so much of my time that it attracted the attention of my son, who asked me the object of my study. I told him I wanted to improve the instrument so that it would crush the largest and strongest stones in the human bladder, which, by general consent, were now relegated to the knife. He asked me how strong these stones were. I said no one knew. He replied that the crushing resistance of the stones must be known in order to properly design a lithotrite for crushing them. On reflecting upon the problem my son made a machine by which both the crushing resistance of a stone and the strength of the lithotrite could be measured. The result is before you in the apparatus now exhibited.

Upon testing different kinds of lithotrites with this machine we were able to find out all the weak points. The result was an entirely new instrument, which will be explained.

My first experiment was made on a fragment of stone taken from the bladder of a horse, which broke one of the usual form of lithotrites, the septum of male blade giving way. I obtained as may specimens as I could in order to measure the strength of different varieties of stones. My colleagues at the Jefferson College loaned me the collection of stones from that institution, and friends loaned me some—their names are recorded in the table—so that I succeeded in getting together a total of one hundred and eighty-four stones, as follows:

Oxalate of lime	55
Phosphate of lime	64
Uric acid	27
Oxalate and phosphate mixed	15
Uric acid and phosphate mixed	8
Uric acid and oxalate mixed	7
Oxalate, phosphate, and uric acid mixed	4
Combustible, requiring further examination	2
Carbonate of lime and oxalate	1
Cystin	1
Total	184

Attention is called to the large percentage of oxalate of lime calculi in the above table. This is accounted for by the fact that these have been better cared for by their collectors, when stones less rare were lost or not kept.

With regard to the strength of a stone in its different diameters, I found by experiment that for the most part the short diameter of the stone is the strongest. It seems strange that an oval versical calculi should have greater resisting power in its short than in its long axis. Perhaps the arrangement of its superimposed layers would account for this.

The increased resisting power of some specimens is to be noticed. Thus in a smooth oxalate of lime stone weighing 116 grains, it took 162 pounds to break it, or nearly a pound and a half for each grain. (This stone is accompanied by a slip of paper stating that it was taken from a

child eight years of age.) Now compare this stone with another, weighing 915 grains (1 ounce and 435 grains) and taking 406 pounds to crush it. Now, if the strength of this stone had increased with its size and it had taken as many pounds in proportion to crush it as the first stone of 116 grains, it would have required an enormous force (about 1,280 pounds).

The truth is that as a stone increases in volume it does not require as many pounds per unit of weight to break it as a small stone. I wish to state that this second stone, taking 406 pounds to break, and now weighing 1 ounce and 435 grains (915 grains), was taken out by lateral lithotomy in 1853, and weighed at that time 955 grains, showing a loss of forty grains, owing to drying. I make no doubt that in this stone the colloids have hardened like cement, and increased the crushing resistance of the specimen. Since our instrument has broken the hardest of these dried stones, I have no doubt that it will break any to be found in the human bladder.

My son, Mr. John S. Forbes, will explain the testing machine and the construction of the new lithotrite.

Mr. John S. Forbes: This apparatus now exhibited was constructed to hold a lithotrite and measure its strength as well as to measure the crushing resistance of vesical calculi as crushed with a lithotrite. The resistance is shown until it broke and the number of pounds pressure when it broke. The apparatus consists of a rigid frame of wrought-iron pipe, upon which is an adjustable cast-iron bridge. The instrument to be tested is placed in the apparatus, and its handle is firmly grasped by a universal brass clamp. The screw-handle of the lithotrite is held in an independent four-jaw chuck, attached to the end of a rotatable shaft, turning on ball bearings, for reducing friction to a minimum. The shaft has also an end movement of about 1¼ inches. Upon the middle portion of the shaft and between the ball bearings is a flat, grooved brass wheel, so arranged that it may be turned independently of the shaft or locked to it. Secured to the wheel is a cord which passes over an overhead grooved pulley, and is provided at its dependent end with a pan for the reception of weights. The friction due to turning the wheel and its accompanying parts and weight of the pan is eliminated by attaching a small bottle containing shot. The operation of the apparatus is as follows:

A lithotrite is placed in position and its cylindrical handle clamped with the brass clamp on the cast-iron bridge. The screw-handle is secured in the four-jaw chuck on the rotatable shaft, and the whole gotten into perfect line and accord. By locking the instrument and turning the wheel over to the right, the male jaw of the lithotrite is propelled forward, together with the shaft, chuck, and wheel, and by reverse motion the instrument is unlocked and the male jaw may be slid backward or forward, just as the instrument is operated in the hands. Having the instrument thus held, we can measure the resistance of a calculus grasped between the jaws of the lithotrite, and, secondly, we ascertain what pressure may be obtained between the jaws without injury to them or any other part of the lithotrite. A dynamometer is arranged so as to measure progressively the amount of pressure exerted by the jaws of the lithotrite by successive addition of weights in the pan. Knowing the relation or coefficient thus established, the stones to be tested are placed in the lithotrite, and the amount of force required to break them established. Theoretically, the power might be estimated by the following formula: $P = p \times c \times w$, in which P = the pressure between the blades; p = the pitch of the screw in number of turns per inch; c = the circumference, in inches, of the wheel of testing apparatus; w = the weight in the pan of the testing apparatus.

Thus it will be seen that the forces are inversely as the paths.

Now this will give us the theoretical pressure between the jaws, but we must consider the friction in the lithotrite arising from the screw-thread and the tendency of the male blade to buckle. In order to obtain this friction we place a dynamometer or other pressure-recording instrument between the jaws, and apply weights to the pan of the testing apparatus. In this way we will get the coefficient or ratio of friction in the lithotrite to the weight applied for various pressures between the jaws. We can therefore lay out a table of actual frictions for each pressure. The formula must now have the factor of friction introduced, and it may be expressed thus:

$P = (p \times c \times w) - (F\,w)$, where in F = the friction per pound corresponding to the weight w. The dynamometer is now removed and we are ready to measure the crushing resistance of any given calculus. A table of crushing resistance of vesical calculi was obtained in this way. In order to obtain the second and third objects, viz., the pressure which may be obtained between the jaws of the lithotrite without injury to any part of the instrument, and what pressure and where the instrument will first give way, we again make use of the dynamometer and apply weights to the pan of the testing apparatus until something happens, for something is bound to occur if we apply enough weights. The dynamometer ceases to move when this event takes place, and we read the ultimate pressure which the now useless lithotrite was able to record. In this manner the table of the strength of various lithotrites which is before you was obtained.

This new lithotrite somewhat resembles the Civiale, Thomson and Bigelow instruments in general shape, and in having a movable male blade. As regards the mechanism and construction the Forbes instrument is entirely different. In the first place the cross-section of the female blade, of usual construction, the groove is shaped so that when great force is exerted the tendency is to spread apart the sides of the groove, allowing the male blade to rise up. In the new lithotrite the groove has a V-shaped or dove-tailed flange on each side, so that this accident cannot occur. The shank is stronger, the bulk of the metal being put above the slot. The septum of the male blade is unusually thick. The shoe of the female blade is spread so that it will not catch the wall of the bladder, and also to allow the *débris* to come out. The surface of the male jaw presents a median cutting edge beveled to each side, with two cross-ridges on the surface to prevent bursting a stone and injury to the bladder by flying fragments. The spur rises to an unusual height on the male jaw for greater strength. The handle of the instrument is entirely new. The instrument is unlocked by simply turning the handle half a turn to the left, which releases the male blade; it is immediately locked by reversing the motion of the handle. The thread on the screw has the advantage of increasing the power and of giving the stone time to break without unduly straining the instrument.

The handle or screw mechanism belongs to what is known as the interrupted screw type. It consists of an internally screw-threaded barrel having the threads cut away the entire length of the barrel at alternate spaces of ninety degrees each.

This screw-barrel has an end movement in the cylindrical handle of about one-sixteenth of an inch. Working in this barrel is a pair of screw-blocks, likewise having their screw-threads interrupted at alternate spaces of ninety degrees each. Thus the screw-blocks may be slid up and down the barrel without the threads engaging. When it is necessary, however, to apply the power, the screw-blocks are turned by means of the screw-handle, and the threads engage immediately. One screw-block is rigidly keyed to the screw-handle shaft, and the other is so formed that it may have a motion of ninety degrees around the screw-handle shaft. Thus when the screw-handle shaft is turned to the right the screw-block that is rigidly attached to the shaft is brought into mesh with the threads of the screw-barrel, and a further turn of the handle of ninety degrees brings the rotatable screw-block also into mesh. The screw-threads on these two blocks are, therefore, now no longer interrupted, relatively to the barrel, but continuous, and we have in substance a solid plug, or screw-block, engaged with the threads in the screw-barrel. As long as the screw-handle is turned to the right this state of affairs continues, and the male jaw is propelled toward the female jaw. After the calculus is crushed the instrument may again be unlocked and the jaws separated by turning the screw-handle to the left until it stops. This left-hand motion is never more than half a turn. Owing to the sixteenth-inch play of the screw-barrel in the cylindrical handle it readily adjusts itself to engage with the thread of the screw-block, and the calculus is, therefore, never dropped in locking the instrument. The screw-handle has been made larger than heretofore, because it aids the easy and gentle manipulation of the instrument. The shape of the handle is also different, and calculated to serve its purpose. Being made of very thin sheet-metal it is at once strong and as light as the lightest handle

now employed, which is, perhaps, the soda-water-fountain wheel of Thomson or Civiale. I have designed a mechanism which may be placed within the hollow screw-handle, whereby the operator can see what power he is exerting between the jaws of the lithotrite. This mechanism, though it will add a trifle to the weight of the lithotrite, will not increase its size in any part. To sum up this instrument, it may be likened to a chain in which each link is of equal strength, and that means the maximum strength for a given size and weight, or, in other words, a correct disposition of metal.

On testing this instrument it was found that up to six hundred pounds it would not suffer any injury; the blades yielded a little at this point, but regained their original position by the natural elasticity of the metal when the strain was removed. Above this point they did not spring back. The extremity of the jaws were grasping the dynamometer when this occurred. But it was found that this amount of pressure was more than could be obtained by the hand, and therefore this accident would not occur in an operation. Moreover, it was found that the blades closed completely and could be withdrawn from the bladder. The greatest power exerted simply by the hand with this instrument was five hundred and forty pounds. While not sufficient to injure the lithotrite, it is more than sufficient to break any stone occurring in the human bladder.

The screw-thread is large, but is a slow thread. It was found that a stone might resist a pressure for a moment, but then it would break without increasing the force. There is an advantage, therefore, in a slow thread, as it gives the stone time to break, as well as increases the power. There is a great loss of power in friction in all lithotrites. In this instrument the friction is greater, but actual amount of force nearly double that exerted by the ordinary patterns with which it has been tested and compared.

DISCUSSION.

DR. MARTIN: It seems to me that this lithotrite has many points of advantage over all others. The handle is easy to grasp. It is not liable to break. The shape of the jaws makes it not easy to block up. Its chief advantage, however, is the easy way of engaging the stone and of going on to crush by simply turning the handle. The surgeons present should express their gratification and thanks to Mr. Forbes for his ingenuity and skill.

DR. WILLIAM J. TAYLOR: I think the instrument the best I have seen.

DR. G. G. DAVIS: If I understand correctly, the screw of this instrument has a narrower thread and exerts more power than the other instruments. As the pitch of the screw increases the amount of power decreases.

MR. J. S. FORBES: Technically expressed, the fact is generally stated that "the power is inversely as the paths."

DR. DAVIS: My point is this: if the surgeon is able to exert more power with this instrument, then it should be more liable to break than other instruments with which less power can be exerted.

MR. FORBES: The instrument is made stronger than the others.

DR. MARTIN: I would like to ask about the grasping of the smaller fragments. From the shape of the male blade, it strikes me that it would not be so liable to engage the small fragments as the Bigelow instrument.

MR. FORBES: It does the work and crushes the stone and the fragments as indicated by this specimen of uric-acid stone.

DR. WM. S. FORBES: Dr. Martin has asked a very pertinent question to the subject of the discussion. I have used this instrument within the last five months ten times. I broke this stone with the 33 instrument. I did not wish to pulverize any more than to permit the pieces to come through the canula. I only wished to crush so that the fragments would be a little smaller than the canula. Any further crushing is a work of supererogation: the patient is kept longer under ether, the instrument is kept longer in the bladder than is necessary, and the instrument is subjected to additional strain. The object is to get the stone out of the bladder, not that it should necessarily be pulverized.

The object of this instrument is to extend the field of litholapaxy, and at the same time a more convenient and useful modification has been made in the mechanism of the lithotrite. By changing the shape of the jaw and carrying the spur a little higher I have increased the power to grasp large concretions, and by widening the shoe we avoid impaction and, as I have

seen, splitting the penile urethra through its entire extent by a Thomson instrument. I know of such a case, a man, seventy-six years of age; five years later his wounds had not yet healed.

In reply to Dr. Davis, I would call his attention to the increased strength of the septum and of the female blade, as well as its oval form and novel groove, by which a common accident with other instruments is avoided; I mean spreading of the slot and permitting the male blade to escape.

Dr. Le Conte reported

THREE CASES OF ABDOMINAL SECTION FOR TRAUMATISM.

(See page 716.)

Dr. Steinbach reported a case of

GUNSHOT WOUND OF ABDOMEN AND LUNG.

(See page 719.)

Dr. T. S. K. Morton reported a case of

GUNSHOT WOUND OF LIVER AND LUNG.

(See page 720)

DISCUSSION.

DR. EDWARD MARTIN: Aside from other considerations the fact is worthy of note that Drs. Le Conte, Steinbach and Morton have been willing to report cases of cœliotomy for gunshot wound involving the abdominal contents, in which the result was not always favorable. It is certainly the exception to find any but the successful cases reported. Hence the results of a statistical study of this subject are most misleading. Thus in the admirable tabulation of Dr. T. S. K. Morton, published some years ago, the percentage of recovery after surgical intervention was so favorable that the inference as to the duty of every surgeon to operate at once on all these cases was direct. When all the cases operated on in a given section, New York, for instance, were collected, including those which were not published, it was found that the mortality was about the same for the cases treated expectantly, *i.e.*, where operation was performed.

Reclus and Nougues, exploiting their sides of the subject, *i.e.*, conservative treatment, deduced as the result of their statistical study the fact that the mortality after penetrating gunshot wounds of the abdomen is about twenty-five per cent. This is manifestly misleading, the result being due to the fact that only the rare successful cases of conservative treatment are published.

It still remains an open question as to whether a patient with a penetrating gunshot wound of the belly has not a better chance for recovery without operation, unless there should happen to be present a skilled abdominal surgeon armed with all the appliances of his art.

The importance of this consideration of the question rests upon the fact that the country doctor or country surgeon whose experience has been limited, and who is unable to secure the timely help of a specialist, need not feel that in treating penetrating gunshot wounds of the belly conservatively he is unfaithful to his trust.

As to the diagnosis of these cases, *i.e.*, the diagnosis of penetration, unless this is absolutely assured by leakage of feces or gas, for instance, or by bloody vomiting, or by purging of blood, or other pathognomonic symptoms, or by passing of the probe into the abdominal cavity, the fact of penetration should be definitely ascertained by exploratory incision in the line of the bullet wound before proceeding to a formal cœliotomy in the middle line.

The importance of bearing this in mind was well illustrated by a case which I saw in consultation with Dr. Edward Bidwell, of Vineland, N. J. The patient was a very fat woman who had been shot from directly in front with a 32-caliber pistol. The wound of entrance was a quarter of an inch below the level of the umbilicus and two inches to the left. The patient was vomiting, had a rapid pulse, was tympanitic, complained of peritoneal tenderness upon the left side of the abdomen. The probe passed obliquely downward and backward through about three inches of fat and stopped at the muscles. Apparently the case was a fairly clear one of penetration and visceral wound. Exploratory incision along the track of the ball showed that it ranged downward and backward, penetrated the abdominal muscles one and a half inches above Poupart's ligament, grazed the peritoneum, and buried itself in the muscles of the pelvis. The wound was cleaned and closed and the woman was purged. In this case cœliotomy might have proved most unfortunate.

For flushing out the abdominal cavity the normal saline solution is very much better than plain distilled water. The

latter causes a primary blanching and a secondary acute hyperæmia, as shown by repeated experiments on dogs by Dr. Hobart Hare and myself. The normal saline solution is perfectly bland and unirritating.

As to the method of closing the belly wound there is wide diversity of opinion. Perhaps there is a growing tendency to first stitch the peritoneum with a continued silk suture, then complete the closure stitches taken through fascia, muscles and skin. In any event, except for buried sutures, silkworm gut should be used.

DR. G. G. DAVIS: In a gunshot wound of the intestine the ball oftentimes perforates both sides of the wall, and it makes so many openings that, as Dr. Le Conte has pointed out, the most careful examination is necessary in order that none may be overlooked. This takes so long that, in order to save time, in some cases it would be better to resect as does Murphy with his button, in preference to other methods, such as stitching each separate wound and especially circular enterorrhaphy.

DR. JOHN B. ROBERTS: Dr. Martin has spoken of the possible bad results of gunshot wounds of the abdomen, and said that the mortality is not greater in such cases when left to nature with good nursing than when treated by modern surgical methods. Of course it is difficult to decide this, but my own impression is that it is far better to open the abdomen in all penetrating wounds. If the operation be done by modern methods the result is, I believe, much better than can be obtained by expectant treatment. Under the old methods nearly all penetrating wounds of the abdomen caused death. I recall, however, one case of gunshot wound that recovered when such abdominal operations as we now perform were unknown. The patient was treated expectantly and did not die. His recovery, however, was regarded by the surgeon who saw him as very unusual. I, personally, am strongly in favor of section as soon as it is proved that the ball has entered the abdominal cavity. I believe in cutting down upon the bullet track to establish the fact that the missile has entered the abdomen, as was done in Dr. Steinbach's case, and then making an incision in the middle line.

Dr. William J. Taylor reported a case of

FEMORAL EPIPLOCELE IN A WOMAN—RADICAL OPERATION.

I wish to present a specimen of omental hernia, removed to-day with the assistance of Dr. T. S. K. Morton. The history is briefly as follows:

A woman, aged forty-six years, had first noticed a lump in her right groin twelve years ago, but it gave no trouble until about four or five months ago, when it enlarged and became very painful. She was in the country at the time, and went to bed and applied poultices to the swelling. In a few days she was much improved, the pain and swelling relieved, but the mass did not disappear entirely. She came to town, and I saw her first ten days ago. There was a good deal of swelling above Poupart's ligament and in the inguinal canal on the right side. I was in doubt whether it was a new growth or a hernia. With rest in bed and care the amount of inflammatory thickening was very much reduced. To-day I made an incision over the tumor and came down upon a very hard tense sac, which easily dissected away, and I came upon this mass just above the internal inguinal ring. I then opened the sac and drew out the omentum until I came to a healthy portion, and put a ligature around it and removed this mass. The sac was dissected free from the adhesion and ligated with silk. The whole mass showed evidence of long-standing inflammation. When I came close to the abdominal ring I discovered that it was a femoral hernia. I drew the edges of the canal together with two sutures, without injury to the artery; during the operation only one small vessel required ligation. The specimen presented is the mass of omentum, which is glued together by inflammatory adhesion and a portion of the sac.

Pregnancy at Fifty-nine.

Dr. Depasse reports that he was called to an aged-looking woman with white hair, supposed to be suffering from a large uterine fibroid, whom a careful examination proved to be pregnant. She was confined of a boy at full term and was able to nurse him. She weaned him on her sixtieth birthday. She was a widow with a forty-year-old married daughter.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for November. Dr. Charles K. Mills, Professor of Mental Diseases and of Medical Jurisprudence in the University of Pennsylvania, etc., contributes a paper entitled

The Relations of Infectious Processes to Mental Disease,

in which he states that conclusions may be drawn as follows:

1. Specific infection must be included among the causes of mental symptoms and diseases which precede, accompany, or follow febrile and other infectious disorders.

2 Much negative evidence can be adduced in favor of acute delirium or acute mania being due to toxæmia—such evidence as is afforded by autopsies which reveal neither gross nor histological change lesions; and in these cases the toxæmia probably overwhelms the patient before the production of meningitis or other disease.

3. Analogies with nervous affections which are known or believed to be of microbic origin—such as multiple neuritis, myelitis and chorea—favor the new view that insanities with similar or related phenomena and lesions are also microbic in origin.

4. The evidence afforded by careful bacteriological investigation of cases of acute insanity is thus far meager, and shows that various micro-organisms may induce the same or similar types of mental disease.

5. The mental disorders of pregnancy and the puerperal state are probably, in a considerable proportion of cases, toxæmic, without reference primarily to childbirth; but it cannot be regarded as proved that a bacillus of either eclampsia or puerperal mania is the sole cause of these affections.

The Nature and Treatment of Leprosy

is discussed by R. H. L. Bibb, M.D., of Saltillo, Mexico, the author coming to the following conclusions:

1. That leprosy is a specific disease, due to the presence of the lepra bacilli.

2. That leprosy is influenced by race, climate, soil, food, etc.,,only in so far as these environments tend to enervation on the one hand or to physical well-being on the other.

3. That experiments have not demonstrated leprosy to be inoculable on man or beast.

4. That leprosy is hereditary.

5. That leprosy is contagious, infectious and communicable under conditions not yet understood.

6. That leprosy is both mitigable and curable.

7. That chaulmoogra oil is a drug of unquestionable value in the treatment of leprosy.

8. That leprosy may be completely eradicated from the list of human ills.

J. W. Markoe, M.D., and Samuel W. Lambert, M.D., Attending Physicians to the Society of the Lying-in Hospital of the City of New York, contribute a

Study of Methods of Obstetric Instruction.

After reviewing briefly the history of obstetrics and the various methods of teaching in use in Europe and America, the authors give the following as the outline of an ideal course of obstetrics:

1. Theoretical lectures as given in the United States.

2. Recitation system as practiced in the same.

3. Manikin course as given in France, Germany and very generally in America.

4. Touch course on pregnant women as universally conducted in France and Germany, at present beginning to be used in the United States.

5. Practical work in hospital wards, not limited to simple observations, but each student actually to carry on the labors and their subsequent treatment under rigid supervision.

6. Clinical lecture on the same material as given in France and Germany, and almost absolutely neglected in America.

7. "Polyclinic" or out-patient department as carried on in England and partially introduced into the United States.

The general result to be gained is: First, as thorough a theoretical knowledge as possible by the first three theoretical courses just outlined above. Secondly, the student should receive as complete a practical application of this knowledge as may be by seeing experts conduct confinement cases. Then, by doing the same under expert direction in hospital wards, where every facility for cleanliness and nursing is at hand, his flagrant errors would be corrected and his unskilled hand begin to appreciate minute details. He should finally put in practice in the tenements, but under careful supervision, the principles he will have learned. This object should be accomplished by the four final practical courses of the ideal system already outlined.

The questions involved in any plan for instructing midwives are similar, but infinitely more difficult to answer. The deepest foundations on which to build up a system are absolutely wanting. The first help should and must come from the State. A law compelling midwives to give evidence of some little knowledge to the local boards of health would compel these women to seek an elementary education in midwifery. If the demand should thus be created the proper schools would soon follow. The raising of

the standard of requirements for registration would then become a mere matter of subsequent detail.

The remaining papers in this issue are "A Contribution to the Localization of the Muscular Sense," by Dr. M. Allen Starr and Dr. A. J. McCosh, of New York; "Tuberculosis of the Fallopian Tubes," by Charles B. Penrose, M.D., and H. D. Beyea, M.D., of Philadelphia.

PERISCOPE.

MEDICINE.

The Cause of Death from Chloroform.

Heart weakness is so generally assumed to be the first warning of danger in chloroform narcosis that during the anesthesia the pulse is more closely watched than the breathing. That chloroform has no direct action on the heart, however, and that it kills by inducing respiratory paralysis, is the conclusion of Surgeon Lieutenant-Colonel Lawrie, as reported in the *British Medical Journal* for July 7th. At a recent meeting of the Royal Medical and Chirurgical Society he contended that the experiments, including those performed under the auspices of the Hyderabad Commission, proved that death from chloroform was due to respiratory failure, and that the practical point to remember during its administration was that the condition of the pulse was quite subsidiary, but that the state of the respiration should be closely watched. Chloroform being an irritant, protoplasm is irritated and destroyed by either its liquid or its vapor. When it is injected into the substance of a muscle, such as the heart or the biceps, motion is arrested in the same manner as it is by hydrochloric acid or any other irritant. He argued that in poisoning from the inhalation of chloroform this irritant action could no more take place in the heart than in the biceps, and hence might be ignored in considering the clinical question of accidental death under this anesthetic. In his experiments with animals, chloroformed blood sent to the heart alone produced no effect whatever, but when it was sent to the brain alone the narcotic acting on the brain centers produced its usual effects. From tracings of the pulse and of the breathing, he demonstrated that chloroform anesthesia without respiratory complication was free from risk.

From much experience with chloroform, Mr. Horsley also was convinced that it was the arrest of respiration which resulted in death, and that in the majority of cases of danger inversion of the patient and artificial respiration would cause recovery. Mr. Gaskell and Mr. Shore agreed that respiration failed first, but held that chloroform had a direct action on the heart also. Dr. Lauder Brunton's experience was that chloroform always paralyzed the respiratory center before enough had been taken to paralyze the heart. A number of the accidental deaths were due, not to the chloroform, but to the operation itself, to asphyxia, or to noxious substances circulating in the blood. Mr. Lawrie concluded by stating that he had found it impossible to teach careless men to administer chloroform safely, and that heart failure might be indirectly produced by stimulation of the vagus through irregular breathing. He had noticed no difference in the effects of chloroform on different races or nationalities. In seven hundred cases of chloroform narcosis the pulse had been carefully watched, but it had given no reliable indications of danger.

On the Use of Sublimed Sulphur as a Local Application in Diphtheria.

C. H. Baumler again calls the attention of the profession to the value of the local use of sulphur in the treatment of diphtheria. He has used it in his hospital practice for many years, and thinks its effects infinitely better than those of any other local application which he has used. He was first induced to use it by the recommendation given to it by Professor von Liebermeister ("Special Pathology and Therapeutics," Leipzig, 1885, vol. i, p. 232), who advises it to be applied abundantly in form of the dry powder to the diseased mucous membrane by means of a soft camel's-hair brush, the application to be repeated every hour or two hours, or only three or four times a day, according to the severity of the case. The action he considers merely a local one, and he thinks its principal field of usefulness will be diphtheria of the fauces, where it can be applied directly and abundantly. He is unable to give at the present a scientific explanation of its action, but an extensive experience of seven years justifies him in placing considerable confidence in its usefulness and recommending it again to the use of others.—*Brit. Med. Jour.*

The Inexorable Facts of Heredity.

"I have drunk whisky every day for thirty five years," remarked a gentleman of sixty, rather proudly, "and I don't see but I have as good a constitution as the average man of my age. I never was drunk in my life." He was telling the truth, but to learn the whole truth you would have to study his children. The oldest, a young lady, had perfect health;

the second, a young man, was of remarkably nervous and excitable temperament, as different from his phlegmatic father as possible; the third, a young lady of seventeen, was epileptic, and always had very poor health. Did the father's whisky-drinking have anything to do with these facts? The instance may be duplicated in almost every community. Think over the families of your acquaintance in which the father has long been a moderate drinker, and observe the facts as to the health of the children. The superintendent of a hospital for children at Berne, Switzerland, has found by careful observation that only 45 per cent. of those whose parents used intoxicating liquors habitually had good constitutions, while 82 per cent. of the children of temperate parents had sound bodies. Of the children of inebriates only 6 per cent. were healthy. Can any man "drink and take the consequences," or must his children take the consequences?—*Quarterly Journal of Inebriety.*

Tincture Adonis Æstivalis, the New Anti-Fat Remedy.

R. Kesseler further reports on his experience on his own person with tincture of adonis æstivalis as a reducer of corpulency. By taking 10 drops three times a day in lithia water for about a month—with certain interruptions made because, as the author states, he was losing flesh too rapidly—he has lost 25 pounds without experiencing any untoward effect whatever.

The experience of the president of the Tennessee Board of Pharmacy with this remedy is also adduced, and is in accordance with the author's: there has been a decided decrease in weight without any uncomfortable symptoms.—*A. M. S. Bull.*

Pathogenesis of Gout and Diabetes.

It is a well-known fact that in certain diseases, such as arthritis, diabetes, hæmophilia, and others, a hereditary tendency is well marked. According to Scherk, this is due to inherited affections of the glandular nerves of secretion. The symptoms of the disease, however, may not assert themselves till after many years, if, as in arthritis and diabetes, on account of the anomalies of secretion, an abnormal quantitative ratio of certain salts in the blood or modifications in the reaction of the medium happen to be present after a certain time. English authors have observed the connection of the two diseases inasmuch as they have called attention to the fact that certain members of one family may suffer from arthritis, others from diabetes. This shows that both are caused by a similar factor, being due to an abnormal function of the glandular nerves of secretion; the quantitative ratios of the salt combinations, which act as carriers of oxygen, will then be modified, the reaction of the medium has become faulty, and, as a consequence, the process of oxidation and reduction will be at a standstill.

It has been shown that in diabetes it is dangerous to narcotize a patient, the danger being probably due to the increase of oxygen. In the treatment of the two diseases, alkaline waters are of great importance, because the process of oxidation in the organism can go on much easier where there is any abundant alkali. Besides the well-known dietary measures, the attention is to be chiefly directed to increasing the amount of oxygen by exercise in fresh air.—*Aerzt. Rundschau.*

Why People Become Deaf.

It has taken the medical world a great many years to discover that loss of hearing is almost invariably caused by some disease of the throat or nose or both. But very recent researches in these fields have demonstrated this fact beyond question, and it is now admitted by the more advanced medical men that, aside from rupture of the ear-drum, there is scarcely a symptom of defective hearing which is not traceable directly to the condition of the nose and throat.

In view of the new discoveries, ear specialists are finding their occupation gone, save as they make their particular branch an assistant in further investigation. It is said, as we have already pointed out, that the use of smelling-salts is one of the most prolific causes of deafness, operating by weakening the olfactory nerves, and through them the auditory system. All strong or pungent odors should be avoided as far as possible, especially those which act upon the secretory processes and, as the popular expression goes, "make the nose run."—*Medical Brief.*

The Significance and Etiology of the Premature Discharge of Meconium.

E. Rossa (*Archiv. f. Gynak.*, Bd. 46, Heft 2) states that it is commonly believed that the escape of meconium before term is a sure sign that the fœtus is in danger of asphyxia, and is therefore an indication for the hastening of delivery. The author's personal investigations have led him to doubt the correctness of this teaching. In a large number of cases the escape of meconium has no significance of the kind generally attached to it. The cause of the phenomenon is simply increased intestinal peristalsis, which may indeed be due to asphyxia, but may also be due to other less well-defined causes. Among these the principal are diseases of the mother, and particularly gastro-intestinal disorders.

Primary Cancer of Fallopian Tube.

Tuffier (*Ann. de Gynec. et d'Obstet.*) describes another example of this disease, only recognized within the last eight or ten years. The patient was aged 55. She had borne two children, the youngest when 25 years old. Menstruation began at 18 and ended at 51, in 1888. In May, 1892, metrorrhagia and hypogastric pains set in. As they continued she entered the Beaujon Hospital and was placed

in Anger's wards in July, 1892. The right iliac fossa was filled with a solid mass, which pushed the uterus forward and fixed it firmly against the symphysis. Retro-uterine hæmatocele, probably due to a new growth, was diagnosed, and abdominal section was performed on July 8, 1892. A mass of the size of a small fœtal head was removed. It consisted of the right Fallopian tube. The uterus and left tube were normal, the left ovary sclero-cystic. The patient was examined five months later; no trace of recurrence or metastasis could be detected. The tube, pear-shaped, was found full of serum and clots. Its walls were thin and it contained a villous tumor. This growth was mounted on a pedicle a centimeter broad, attached to the walls somewhat inferiorly, and to the inner side of the middle of its course. At the point of attachment of the pedicle the tumor substance perforated the tube wall so that a tubercle as big as a pea projected on the outer surface of the tube The villous mass was an epithelioma, allied to cylindroma; the stroma was very young connective tissue.

Labor and Pregnancy Complicated by Bright's Disease.

As a result of the careful study of numerous cases of labor and pregnancy complicated by Bright's disease, Dr. G. E. Herman, Obstetric Physician to the London Hospital, in a report to the London Obstetrical Society, summarizes as follows:

"There are at least two kinds of renal disease of which a pregnant woman may be the subject and to which pregnant women seem specially liable. One of these is a very acute disease, coming on either without any premonitory symptoms or with premonitory symptoms of very short duration—*i.e.*, usually measurable by days. It attacks chiefly primigravidæ. It often causes intra-uterine death of the child. It is attended with extreme diminution in the quantity of urine, and the small quantity of urine passed is greatly deficient in urea, but contains enough albumin to make it solid in boiling. This is the disease which is accompanied with rapidly recurring fits. If the disease runs a favorable course the fits cease, then the urine increases in amount and the percentage of urea in it rises. If the excretion of urea is not re-established the case quickly ends fatally. Such cases seldom if ever pass into chronic Bright's disease.

"The other is a disease which attacks older subjects, chiefly those who have had children before. Its premonitory symptoms are gradual and slow in the outset—*i.e.*, usually measurable by weeks or months. It less often leads to intrauterine death of the child. It is generally accompanied with increase in quantity of urine, with copious loss of albumin, but not so much in proportion to the urine as in the more acute disease, and with diminution in the amount of urea, but not nearly so great a diminution as in the acute disease. In these patients delivery is followed by temporary increased diuresis and by increase in the excretion of urea. When this increase is considerable the patient usually gets well and the albuminuria ceases. When the increase is only slight the albuminuria persists and the case becomes one of chronic Bright's disease. This form of disease is sometimes attended with fits, but generally not. The presence of albuminuric retinitis affects prognosis unfavorably. When the pressure within the abdomen is greater than usual the amount of urine may be diminished; but in such cases the diuresis and the augmented excretion of urea after delivery are proportionately greater. In the acute disease which causes eclampsia, and in the chronic disease when it is associated with excessive intra-abdominal pressure, much of the albumin is paraglobulin. The cases in which the albumin is mainly serum-albumin generally either die or pass into chronic Bright's disease."

The Dangers of the Long Rectal Tube.

The use of the long rectal tube in obstruction of the bowel has never been looked upon with favor by anatomists. Nothing is more difficult than the successful maneuvering of the rectal tube through the turns of the sigmoid flexure. The question of the value and safety of this tube having been asked of the *British Medical Journal*, the matter was referred to Mr. Harrison Cripps, who replied as follows: "Traditions die hard, and notwithstanding the condemnation of the long rectal tube by Brodie, Treves, and many other eminent authors, I still find that in most cases of obstruction the tube has been introduced. Fortunately, these tubes are fairly soft, so that in a capacious rectum, when they impinge and are arrested about opposite the promontory of the sacrum, they simply coil up and do no harm. If stiffer ones are used the patient's life is placed in imminent risk. A patient at St. Bartholomew's Hospital was to be operated on for ruptured perineum. In order to increase the supposed efficacy of the injection, a quart of soap and water, with some ounces of oil, were injected by means of a long tube. The injection never returned. A few hours afterward, owing to the acute symptoms of the patient, I assisted one of my colleagues in opening the abdomen. The soap and water and oil we found below a reduplicated fold in the upper part of the rectum. The patient died. The idea that these tubes can be generally passed into and beyond the sigmoid flexure is a pure delusion, save in the rarest circumstances. As a means of diagnosis, or of treating stricture beyond the reach of the finger, tubes of any kind are absolutely useless. If a stricture is actually present it would be 100 to 1 against the long tube or bougie entering it, for it would almost certainly catch in the cul-de sac generally caused by the invagination of the stricture. If a stricture be not present, the arrest of the bougie by the sacral promontory leads to delusive diagnosis. Brodie, in his lectures, alludes to a case in which a worthy practitioner had spent over 150 hours in dilat-

ing a supposed stricture situated high up. The treatment had extended over a period of a year. Brodie, who was present at the post-mortem examination, found there was no sign of a stricture, the bougie becoming arrested by a curve of the sacrum."

Copper Arsenite in Therapy.

A number of cases are described by Dr. A. Hedlicka in which he employed copper arsenite locally, with almost universal success in the various acute and sub-acute inflammations of the mucous membranes, attended with pain, suffusion, and more or less watery discharge. He found it most efficient in solutions of 1:50,000–100,000. These solutions are easily made by dissolving a 1-100 grain pellet in 1–2 ounces of water; they are applied at intervals rarely longer than an hour (bladder, urethra, and nose), and frequently not longer than from 10–15 minutes.

The remedy is rather indifferent in cases where the discharge is thick or persistent, unless the affected surface be previously thoroughly cleansed.

The duration of the treatment ranged from a few hours to two or three days in mild cases, from several days to three months in severe cases. The author pretends to have never failed; relief being nearly always instantaneous, no other remedies were needed.—*N. Y. Med. Jour.*

Treatment of Peripheral Neuritis.

Professor Leyden believes that in the case of neuritis following acute specific diseases, care during convalescence as to nourishment, rest in bed, and avoidance of over-exertion contribute to prevent its occurrence. "Etiological treatment" (removal of the cause) in neuritis due to alcohol or lead and treatment of the primary malady as in diabetes is of the first importance. There is no specific remedy for multiple neuritis, and treatment by drugs does not play a very important part. Owing to the fact that rheumatism is not infrequently an element in the etiology, salicylate of sodium and other anti-rheumatic drugs had been used, without producing any good results in the majority of cases. Iodide of potassium was of use only now and then, and mercury was of doubtful value. Antipyrin, phenacetin, exalgin, euphorbia, and methylene blue were sometimes of use for the relief of pain, but it was often necessary to resort to morphine, chloral, sulphonal, etc. Strychnine, formerly much used, but lately fallen into the background, deserved to be tried; by increasing the excitability of the affected muscles it favored the return to normal function and nutrition; it ought especially to be resorted to in progressive cases in which the respiratory movements were threatened. Leyden prefers to use it as a subcutaneous injection, gr. 1-70 to gr. 1.20 twice daily. Massage and baths were valuable auxiliaries which were indicated, especially the latter, in the later stages of the disease. General hygienic treatment was of much importance. Rest—as a rule rest in bed—was of the first importance in the early stage; in the later stage, feeding. Finally, in the latest stages of all, moral suasion, rousing the patient's latent energies, was often of great value. Passive movements and encouraging the patient to make active movements were generally attended with better results than massage in this stage. Electricity, formerly used too much, was now used too little, but its usefulness was greatly limited by the fact that in many cases the pain caused was too great to permit the treatment to be continued.—*Berliner Klinische Wochenschrift.*

"Thyroidism," Graves' Disease, and Hysteria.

In a paper read before the Societe Medicale des Hopitaux, M. Beclere pointed out the relationship between "thyroidism," Graves' disease, and hysteria. He had recently treated a woman suffering from myxœdema with sheep's thyroid. She had, through a mistake at the outset of the treatment, taken as much as ninety-two grammes of thyroid gland within a period of eleven days. This excessive dose had been followed by symptoms now recognized as due to "thyroidism"—viz., tachycardia, irregularity of pulse, rise of temperature, insomnia, restlessness, polyuria, glycosuria, albuminuria, and incomplete paralysis, with sensation of heat and sweating. M. Beclere further noted an increased rate of respiration, transient tremor of arms, and exophthalmos. Hence arises the question whether these symptoms, which also characterize Basedow's (Graves') disease, may not be due in that affection to hypersecretion of the thyroid gland. It may be recalled that this was the question taken up by Professor Greenfield in his Bradshaw Lecture last year. Moreover, M. Beclere observed in the course of the treatment that the patient manifested some hysterical symptoms, such as transitory aphasia, monoplegia, and anæsthesia of the right arm; and he asks whether an excessive secretion of thyroid juice may not be one of the provocative agencies of hysteria.—*Lancet.*

Treatment of Precocious Malignant Syphilis.

Fournier (*Brit. Derm. Jour.*) states that the tertiary accidents of syphilis may be met with in any year of the existence of the syphilitic subject dating from the primary chancre. These accidents are most frequent in the course of the third year. Statistics indicate that even the second year is very prolific in tertiary phenomena; indeed, more than any except the third. Even in the first they are often met with, and these constitute syphilis maligna precox. These lesions have special characters; so definite are they sometimes that at a glance the diagnosis of early malignant syphilis may be established. Thus the lesions ulcerate and spread rapidly; they are present in large numbers and disseminated; they necrose deeply and very markedly;

they are particularly rebellious to specific treatment, and are accompanied by a very bad condition of the general health. The local management consists in getting completely rid of pus and scabs, cleaning antiseptically with boric-acid baths, boric vaseline, or boric compresses. When thoroughly antiseptic the limbs should be surrounded with a wet dressing of boric alcohol, and on the superficial ones mercurial plaster, changed daily. Internally, if much prostration and anæmia, Fournier avoids mercury for the time and prescribes tonics. He gives quinine or small doses of iodine in extract of krameria. The food is regulated, milk given to drink, and the urine watched Potassium iodide is administered. Fever and insomnia must be combated. Generally by this treatment alone strength is gained, fever disappears or lessens, and prostration is recovered from; indeed, the ulcers may heal in two or three weeks. When improvement is shown mercury may be tried cautiously.

Treatment of Delirium Tremens.

In the New York *Medical Journal* Bellamy concludes an article as follows:

1. Delirium was controlled with greater rapidity and safety by trional than by other hypnotics.
2. In the majority of cases a marked stimulant effect was observed, possibly on account of the methylic and ethylic elements which enter into the composition of the drug.
3. On account of the low temperature noted in all cases, trional must possess antipyretic properties, thereby simulating its allies of the phenol group.
4. It was always well borne by the stomach, and in one case was rapidly absorbed when administered per rectum.
5. No unpleasant after effects were observed, and in all cases recovery was speedy, with the exception of two.

Bicycle-Riding for Women.

After pointing out certain contraindications, the *New York Journal of Gynecology and Obstetrics* says, editorially: "But there are a certain number of women in this country, even among those long past puberty, who, hard as it is at times to realize it, have never had any pelvic disease whatsoever, and it will be in regard to these that we shall be called upon to answer the question: Is bicycle-riding beneficial for women? We are inclined to think that, under these circumstances, it is. The muscular action is much more regular than in horseback-riding, and the danger of accident, for a good rider, far less. For women past the menopause, with a tendency to excessive flesh, to torpidity of the liver, to constipation and to dyspepsia, it should be of especial benefit. But we fear that in this class of cases, in which it would appear to be most indicated, the power of feminine vanity will ever place a bar to our converting a probable theory into practical experience.

"At all events, there is no other form of exercise within the capacity of the average woman which involves so general a muscular development and glandular action combined with a healthy mental and physical exhilaration."

The Dangerous Anti-Vaccinationists.

One of the most striking testimonies to the mischief that a knot of anti-vaccinationists can do is shown in the experience of Stuttgart, the capital of Wurtemberg, between the years 1864–1869. Stuttgart was the local point from which radiated anti-vaccination influence, and, in consequence, not only many private citizens but the militia of that city were "unprotected." It had a population of 1,760,000 souls less than New York, yet in the five years indicated there were no less than 11,092 cases and 800 deaths. During that time there were 34 cases in the army of the whole country, but not a death; and now that vaccination and revaccination are not only compulsory, but done under a faithful inspection, the German army is the bright, conspicuous example, shining like a beacon, for all the world to follow. If Germany could build an impassible fence between herself and Russia, the whole country would soon show itself completely freed from the pest; but there is always an immigration from Russia into Germany of persons from that land, where the persistence of cholera shows the inability to cope with epidemics.—*Mrs. H. M. Plunkett in the Sanitarian.*

Scleroderma.

Eulenberg (*Wiener medizinische Wochenschrift*) cites several cases of this disease, one of which ran a fatal course in two years and began with symptoms of tabes. Later the diagnosis was trichinosis, due to the swelling of the eyelids and the muscles. Still later the diagnosis was polyneuritis. Errors in diagnosis are especially frequent when the disturbance begins in the proximal ends of the limbs. Then the characteristic signs of the disease, the tense pain, the paresthesia, the cold sensations, etc., are looked upon as signs of a nervous disturbance. In a fully developed diffuse scleroderma, of course, there can be no doubt of the diagnosis. In the beginning of the disease the marked stretching of the skin, the mask-like condition of the features, and the enlargement of the hands and feet are characteristic. The disease is rare, occurring between twenty and fifty-two years in the cases observed. The clinical symptoms are marked by disturbances of sensation. Sometimes there is motor disturbance, but this is seldom. There are many trophic disturbances, however. The face may become atrophied and spots of ulceration occur. In the small joints there may be enlargement of the ends of the bones. The excretion of sweat is sometimes but not always diminished. The general symptoms which occur in the most severe cases are loss of flesh and strength. There are no pathological lesions found in either the cord or the peripheral ganglia or nerves.

Apocynum Cannabinum in Heart Disease.

A. G. Glinski (*Vratch*), after having proved by experiments on cold-blooded and warm-blooded animals that the root of the apocynum cannabinum contains a strong poison which in large doses paralyzes the heart, and when given in small quantities retards and strengthens its beats, decided to take it himself, as he is suffering from hypertrophy of the left ventricle, with intercurrent attacks of dilatation of the organ, mitral murmur, dyspnœa, etc. The dose was 15 drops of the fluid extract three times a day. As he found that all his symptoms disappeared in two days, he gave it also to other patients in the same quantity in cases of palpitation, disturbed compensation, in which strophanthus and adonis vernalis had failed and digitalis seemed contraindicated. He gives a full account of some of his cases, and summarizes his experience in the following conclusions:

1. The action of the root of apocynum cannabinum is similar to that of digitalis without being cumulative.
2. In cases of dilatation the fluid extract rapidly diminishes the area of dullness.
3. It increases the daily amount of urine, stops the palpitation, and promotes the absorption of transudations.
4. With the exception of increased pulsation of the arteries of the head, it has no bad secondary effects. It was used either in the form of a decoction (1 drachm to 8 ounces), three to four tablespoonfuls a day, or tincture (1 in 10), 5 to 10 minims three to four times daily, or fluid extract in doses of 10 minims to half a teaspoonful three times daily.

Night-Sweats—Treatment.

The July number of the Brooklyn *Medical Journal* contains a valuable report on the treatment of night-sweats of pulmonary tuberculosis. Only individual drugs were employed for the purpose named, and while many were subjected to the test during a period of five years of clinical experimentation, but eight proved successful to any practical degree. Among those having more or less therapeutical value were aromatic sulphuric acid, camphoric acid, chloralamid, muscarine, oxide of zinc, atropine, tincture of belladonna and agaricin.

The latter drug, according to the reporter, Dr. Henry Conklin, ranked first, and concerning it he comments as follows:

This was the most successful of all the drugs. It produced most excellent results in young subjects. Under its use the skin remained in a dry condition, without suspicion of any kind of cutaneous activity. It was very successful in cases where, during its use, the sweating had disappeared and had returned after the drug had been discontinued for a time. Repetition did not weaken its power. Of all the remedies, it acted best in the first few administrations. Subsequent ones sometimes failed. It can be used for any length of time and has no disadvantages.

Agaricin was given in pill form, gr. 1-12; one pill at bed-time, or a pill late in the afternoon and a second in four or five hours. This remedy diminished the sweating in one-eighth of the administrations, stopped it in three-fourths, and failed in the remainder.

The Relief of Spasmodic Retention of Urine.

Excessive irritability is one form of interference of the higher centers; the other form is spasmodic retention. Thus when a man wishes to pass water he is anxious, especially if some one else is standing by and waiting, as in a public urinal, to make water in a hurry; the desire to make water quickly prevents him from passing it at all. This form can frequently be relieved by some such plan as that adopted by Boerhaave. He lived before taps were so common as now, and he used to have a screen in his consulting-room behind which was placed a tall footman. When he desired any of his patients to pass water, the footman, at a given signal from him, poured water from a water-bottle into a basin on the floor, so as to imitate the sound of a person passing water, and this at once had the desired effect. If in the out-patients' department you want to get a specimen of water quickly, in order to examine it, the best thing you can do is to turn on a tap, and if that is not sufficient leave the patient to himself and tell him there is no hurry whatever. As a rule, if there is more than two teaspoonfuls of water in the bladder, you are sure to get it by this plan. Sometimes, also, when there is no water running, if the patient only thinks of the sound of running water it will make the bladder act. The introduction into the uninals at railway stations of constantly running water has been of great service to many. Some passengers can now empty their bladder at a railway station who could not have done it before, although it does not occur to them that the constant running of water has anything to do with the evacuation of the bladder; it has, however, a great deal to do with it. Washing the hands with cold water is another help, as also the application of a cold wet sponge or hot water to the perineum; and making the patient sit down in a hot sitz-bath will frequently enable him to pass water into the bath when he could not do it otherwise.—*N. Y. Med Times.*

SURGERY.

Abrasions of the Skin.

Tinct. benzoin comp. is of especial value, according to Dr. J. L. G. Sherrill (*Amer. Therapist*), in abrasions of the skin, in conditions such as chapped hands, lips, fissured nipples, etc. It is also of service in eczema where there is a tendency to cracking. The peculiar benefit to be derived from its use in such conditions lies in the fact that after evaporation the gum forms a thin coating over the abraded surface, in this way protecting it from external influences and also from infection. The surgical use of compound tincture benzoin

should be more widely extended. In case of injury about the hand—whether it be slight incision in which suture would not be necessary, or whether it be excessive laceration and contusion, and especially injuries occurring in the use of machinery—he has found the application of compound tincture benzoin to be especially useful. The manner in which it should be used is as follows: After carefully cleansing the wound, removing all foreign substances, irrigating the wound with an antiseptic solution if there is any chance or indication of infection, and thoroughly checking all hemorrhage, a layer of surgical cotton is placed around the wound. If the injury is about the hand the fingers should, of course, be separated and kept apart by layers of cotton. After cotton is applied the compound tincture benzoin is poured down next the surface of the wound, saturating the cotton immediately surrounding the injured tissues. This drug, after undergoing evaporation, will form a coating with the cotton which will hermetically seal the part, thereby rendering it perfectly aseptic. Benzoin in itself is an antiseptic, although of inconsiderable strength. There will be some slight smarting upon the application of this tincture, which, however, will not seriously inconvenience the patient, and which is due entirely to the fact that it is carried by an alcoholic medium.

New Operation for Removal of Enlarged Cervical Glands.

Dollinger (*Centralbl. f. Chir.*) describes an operation for the subcutaneous extirpation of tuberculous lymph glands in the neck and submaxillary region. The posterior half of the scalp having been shaved and the whole of the scalp and the skin of the affected side of the neck carefully disinfected, an incision is made commencing behind the external ear and carried in a curved line with the convexity backward and downward toward the middle line of the neck behind. The skin and superficial fascia are divided, and the anterior and lower flap is undermined by finger and elevator until the enlarged glands are reached; these, if they have not broken down or contracted firm adhesions with surrounding soft parts, may now be readily detached by the elevator and drawn through the wound. The skin forming the lower flap is so yielding, especially in women and children, that it is possible by this operation, the author asserts, to reach glands situated near the chin, and even those in the supraclavicular region. The wound, when made under strict antiseptic precautions, heals quickly, and the scar is hidden by the new growth of hair.

Saline Fluid Subcutaneously in Collapse.

Dr. Harold Williams reports in the Boston *Medical and Surgical Journal* a case of recovery from profound collapse in cholera morbus by the subcutaneous injection of saline fluid. The case had the usual history. Everything else failing, it was decided to try the salt solution subcutaneously.

For this purpose a reversed aspirator was used, and a quart of the solution, containing fifteen grains sodii bicarbonatis and half a drachm of sodii chloridi at 105°, was slowly injected beneath the skin of the abdomen. The injection of this fluid was followed by immediate improvement. The radial pulse became distinctly evident; the respirations became more rapid and full; the surface of the body warmer. From this time there was progressive improvement, and the patient recovered.

A New Method of Shortening the Tendo-Achillis.

Phocas objects to Willet's method ("St. Barth. Hosp. Rep.," 1886) of excising a portion of the tendon for this purpose, and also to Gibney's, in which the tendon is divided, no portion being excised (*Rev. d'Orthop.*, 1880, pp. 217 and 244).

In both of these methods the sutures include the skin with the tendon. The author contends that it is not sensible to divide, much less resect, a tendon which it is proposed to strengthen, and considers it a forlorn hope to attempt to make the cicatrix perform the function of the tendon. He proposes the following method, and reports a case, but one too recent to be considered a cure.

A median incision five or six centimeters long is made over the tendon, the sheath opened and the tendon carefully denuded. It is then transfixed laterally at the upper end of the wound by a bistoury which is carried down the middle of the tendon by a sawing motion. The posterior flap is cut away above and below. The anterior part of the tendon is thin enough to be folded on itself, and this is now done, the freshened surfaces together, thus shortening it one-half the length of the incision, and the fold stitched together with catgut. The sheath is closed, and the skin also, separately. The foot is then put up in equinus in a fixed dressing.—*Rev. d'Orthop.*

Alcohol in Shock.

Dr. Wood is authority for the statement that "alcohol is probably of no value whatever in shock. Indeed, I am perfectly sure that a large dose of alcohol in shock puts one nail in the coffin of the patient, and if you want your patients to come out of shock you will be very careful in giving them alcohol. Alcohol stimulates the heart but paralyzes rather than stimulates blood-vessels." The theory is, "by its action on the blood-cells it checks oxidation and limits the power of absorbing oxygen and eliminating carbolic-acid gas."—*Omaha Clinic.*

Laminectomy.

Inasmuch as considerable has been written of late touching the operation of laminectomy, and as there is still no reasonable uniformity of opinion, the conclusions of Dr. A. Parkin, surgeon to the Victoria Hospital, Hull, England, based upon six recent cases, may well be put forth:

1. That extension and counter-extension of the spine, however carefully applied, has little or no effect on cases of paraplegia.

2. That, as a rule, laminectomy has an immediate effect on the paralysis when due to

caries of the spine, and that most cases so treated recover entirely from their paralytic symptoms.

3. If the tuberculous focus can be eradicated from the vertebræ there is every prospect of the result being permanent, otherwise relapses may take place, or further tuberculous disease elsewhere.

4. It is possible by means of laminectomy to considerably improve cases of severe deformity from spinal disease.

5. That advanced cases of spinal caries, in which it is probable that a caseous mass exists, may be greatly benefited by laminectomy and the direct treatment of the diseased focus.

6. That the operation itself is not a difficult one, unless there is grave respiratory trouble. It does not interfere with the future stability or mobility of the spinal column; the disease for which such operation is performed may, however, do so.—*Brit. Med. Jour.*

Treatment of Tuberculous Peritonitis.

Guignabert describes a method he employs in the treatment of tuberculous ascites which was first suggested by Rendu. It is most applicable to this particular form of peritonitis. It consists in introducing a fine trocar and canula through the abdominal wall, midway between the umbilicus and anterior superior iliac spine. While the flow is diminishing, a hypodermic syringe is five times charged with camphorated naphthol, and the contents are passed into the abdomen, the canula being made use of for the purpose. The puncture is subsequently closed by means of aseptic wool and gauze. Hereafter the peristaltic action of the intestine serves to distribute the naphthol, which produces insignificant pain for only a few hours. Furthermore, during the first few days the temperature shows an evening rise and the ascites apparently increases, though the fluid subsequently disappears. Ultimately masses of adhesion will be felt, and these gradually diminish. During the operation the strictest antisepsis is required.—*Boston Medical and Surgical Journal.*

DIETETICS.

A New Method of Making Palatable and Digestible Milk.

Dr. Robert T. Edes, of Boston, gives a valuable way of preparing milk where other methods have not proved useful:

A pint of milk is gently warmed. Into it is dropped, very slowly and with constant stirring, about twenty minims of the dilute hydrochloric acid of the United States Pharmacopœia. The milk should be stirred until it cools. In this way a very fine flocculent coagulum is produced, floating in the whey, which is easily accessible to the digestive secretions, while the whole fluid has lost somewhat of the flat and cloying taste which makes it unacceptable to so many. It will be noticed that milk prepared in this way differs from the various "wheys" in the highly important particular that the casein is retained and used, instead of being separated out as a distinct product, while it avoids the bitterness of pancreatinized milk.—*Boston Med. and Surg. Jour.*

DISEASES OF THE NOSE.

The Treatment of Deviation of the Nasal Septum.

The septum may be forced into position without the employment of cutting or lacerating instruments (efficacious mainly when the deviation is confined to the cartilaginous portion of the septum), or prominent portions of the septum may be first removed with a suitable instrument, or the septum may be incised with a knife, or straightened by the employment of pins or by fracturing the septum with comminuting forceps. The writer gives an interesting summing up of the instruments and measures used by different writers for this affection, and describes his own forceps for fracturing the septum. Operation is demanded where there is nasal stenosis or where there is pressure between the deflected portion and other parts of the nasal passage. The first step is to place the septum and turbinated bodies on the concave side of the septum in a normal condition. The septum is to be reduced as far as possible to normal thickness. In the majority of cases incisions with a bistoury on the convex side are necessary before using the redressing forceps. Wounding the mucous membrane on the concave side should be avoided. In many cases a twenty per cent. solution of cocaine will be sufficient to render the operation painless, especially with the use of a little chloroform just at the time of fracturing. The septum is held in position by a plug (made by wrapping wool or cotton around a small metal plate) in the previously obstructed nostril. Before and after the operation the nose is cleansed with a saline solution of 1 to 5,000 bichloride of mercury. The dressing may be left *in situ* four or five days before changing.—*John O. Roe in New York Med. Jour.*

DISEASES OF THE EYE.

Reflex Cough Due to Ear Disease.

Lavrand calls attention to the fact that in many patients affected with ear disease a blunt hook, curette, or speculum, when introduced into the internal auditory meatus, provokes cough, which disappears when the instrument is withdrawn. He has obtained this reflex in twenty-one per cent. of all the patients that he has examined. He states that at times, from disease of the auditory canal, the cough occasionally becomes very distressing and persistent. He cites a case reported by Percy Jakins in which there were all the signs of beginning tuberculosis, such

as cough, exhaustion, night-sweats, occasional delirium, and mucous rales throughout the chest. Both meatuses were plugged up with accumulations of wax, and when these were removed the pulmonary symptoms abated. The reflex cough is explained by the anatomical fact that the auricular branch of the pneumogastric has its origin in the jugular ganglion, or is given off from the trunk of the pneumogastric immediately below that situation, and proceeds by way of the jugular fossa and the Fallopian canal to the posterior part of the external auditory canal. Observation has shown that this cough is produced only by irritation of the postero-inferior wall of the canal near the tympanum, and the reason that all do not suffer with auricular reflex cough when disease is present may be in part due to an anomaly of innervation in that particular individual. The author finds no relation existing between the more or less nervous condition of the patient and the occurrence of this reflex. The cough which is produced has no distinct characteristics; sometimes it is paroxysmal, resembling that of whooping-cough; sometimes explosive, short, harsh, and barking, and, unless there is catarrh of the passages, it is not accompanied by expectoration.—*Journal des Sciences medicales de Lille.*

PATHOLOGY.

Inoculability of Carcinoma into Healthy Parts of the Bodies of Cancer Patients.

Two cases are reported, of which the second is of especial interest. The first case was one of carcinoma of the vagina, which had developed upon that point where the vaginal wall was in contact with the cancerous ulcer of the portio. But the other case, carcinomatosis of the peritoneum, developed subsequent to an ovariotomy. Small cancer nodules occurred in almost all of the suture wounds of the abdominal incision, while the incision itself remained unaffected. The theory of "inoculation recidive," which has been so thoroughly considered by Winter, appears to have received additional support.—*Dr. Sippel in Cent. f. Gynæc.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM NOVEMBER 11, 1894, TO NOVEMBER 17, 1894.

By direction of the Secretary of War, the leave of absence granted First Lieut. Francis A. Winter, Assistant Surgeon, in S. O. 71, July 25, 1894, Department of Texas, is extended one month.

By direction of the Secretary of War, the leave of absence granted Captain Eugene L. Swift, Assistant Surgeon, in S. O. 147, October 11, 1894, Department of Dakota, is extended one month.

Leave of absence for one month is granted Captain Benjamin L. Ten Eyck, Assistant Surgeon.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE TEN DAYS ENDING NOVEMBER 15, 1894.

Austin, H. W., Surgeon; to proceed to Boston, Mass., and assume command of service, November 10, 1894.

Irwin, Fairfax, Surgeon; to assume charge of Quarantine Division of the Bureau, November 14, 1894.

McIntosh, W. P., P. A. Surgeon; granted leave of absence for fourteen days, November 9, 1894.

Young, G. B., P. A. Surgeon; granted leave of absence for seven days, November 8, 1894.

NEWS AND MISCELLANY.

Routes and Rates to Winter Resorts.

The B. & O. R. R. Co. has just issued a little booklet giving the routes and rates to various winter resorts in Cuba, Florida, North Carolina, Virginia, New Jersey, Pennsylvania and Georgia. The information is very conveniently arranged and indexed. Copies can be had by inclosing a two-cent stamp to Chas. O. Scull, Gen'l Pass. Agent B & O. R. R., Baltimore, Md.—2t

ORIGINAL ARTICLES.

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., New York.

During the past year (1894) a singularly large number of acute abdominal injuries of the non-penetrating variety have come under my care.

Taken as a group, they presented so many varied and unusual features it occurred to me that a short record of these, with a few others included, would supply a text for a brief study of that interesting and highly important subject, "Abdominal Contusions."

It was my intention at first to embrace within the scope of this review, as a preliminary portion, a series of experiments on the lower animal to be *en rapport* with the tendency of the times, and endeavor to support the clinical side by observations derived from pathological conditions deliberately produced.

This no doubt would lend additional interest and value to the subject, but on reflection I was finally convinced that the additional light imparted by this sort of inductional observation would not compensate for the trouble and the necessary amount of cruelty and suffering imposed. For without the infliction of very great force it would be impossible to rupture any part of the digestive tract of the dog, seriously lacerate the solid fixed organs or the large blood-trunks.

And though this were practicable under anæsthesia, as soon as reaction would set in acute peritonitis with agonizing distress must inevitably have followed. Furthermore, as every one knows who has had any experience in experimental abdominal surgery on the dog, his tissues are of a vastly tougher and stronger consistence and their recuperative energy far greater than in man, it is easy to understand that inferences derived from this line of investigation can at best possess but a relative value when applied to analogous vital structures of the human being. For these reasons it was decided to proceed on data derived solely, so to speak, from "human experimentation," from what knowledge could be gathered from numerous cases coming under my own care, which could be observed throughout from the time of injury until recovery or death; and in the latter event followed to the autopsy room, when the injured structures or viscera could be separately examined under the naked eye.

With a view of enhancing the value of these observations and giving them additional practical interest, the columns of several of the most noted authorities in surgery have been examined, and from them are copied their views and opinions as well as cases that have a pertinency to the subject here considered.

As the study of abdominal contusions is a large one, which to deal with by a systematic plan in full detail would carry one to a considerable length, in the present instance an effort will be made to condense and reduce it within such limits as will not cover too much ground and yet permit a fairly full exposition of it.

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

ANATOMICAL OUTLINE OF THE ANTERO-LATERAL ABDOMINAL WALLS, CAVITY AND CONTENTS.

The anterior abdominal parietes present a convex trapezoid elliptical contour, with an inward slope along their superior and inferior vertical and lateral planes.

If we draw a line from the insertion of the ensiform cartilage above to the symphyses pubis below, we will observe that as the free borders of the alæ thoracis spread outward above a conical outline is presented in the center, the base of which broadens as we descend to the navel, and from below upward the obliquity of the pelvis with the inward inclination of Poupart's ligaments contribute toward an inferior conical terminus, though not so sharply defined as the one above.

Now, if we intersect this vertical line through the center of the abdominal areas by another horizontal, passing through the umbilicus and carried as far back on either side as the inner margin of the erector spinæ muscle and midway between the last floating rib and the crest of the ilium, we will here observe that the lateral terminus on either side takes the form of a cone through the direction in which the outline of the ribs incline and the iliac border broadens as it descends. The transverse or horizontal diameter is slightly greater than the vertical, varying according to the peculiarity of build in certain individuals. Of the three great cavities, the abdominal is least invested by a bony structure. The quadratus lumborum, the psoas muscles, fascia, erector spinæ and lumbar vertebræ contribute a formidable protection from behind; so that concentrated traumatic force cannot often be transmitted posteriorly to the viscera within the peritoneum without serious damage of the lumbar vertebræ or the corda equina being first sustained. The abdomen is practically a large sac, which contains all the essential organs of digestion and excretion, if we exclude the lungs and integuments. This vast pouch is mainly protected and supported anteriorly and laterally by voluntary muscular tissue. The muscles pass in transverse and vertical directions and collectively constitute the "abdominal girth."

The digestive tube, which receives its solids, liquids and gases through the mouth and is drained by way of the rectum, chiefly occupies the abdominal cavity and is most exposed to injuries.

All the solid viscera here are best protected. Normally the greater volume of the liver rests under the shelving dome of the diaphragm, under the ribs on the right side. The spleen rises high under the ribs on the left side and is well protected in health, but the free edge of the liver projects downward in expiration on right or left side, and the spleen only when enlarged. The pancreas is a suspended organ behind the duodenum, resting on the aorta quite out of harm's way, except when such force is applied as first disorganizes the overlying parts.

In the standing attitude the kidney is a freely moving body, rising and falling an inch or more with each respiratory act. This lies behind the peritoneum, imbedded in loose fat on the psoas muscles close to the bodies of the lumbar vertebræ, which though in spite of its protected position, is mostly exposed to trauma of all the solid viscera in the abdominal cavity. Large blood-trunks occupy the posterior abdominal walls, passing on to the lower extremities and from the alimentary canal to the liver. The ureters pass down behind the peritoneum to the bladder; and the thoracic duct which commences on the body of the second lumbar vertebræ and ascends upward through the aortic opening of the diaphragm. The common bile duct courses obliquely downward and inward along the side of the spinal column to enter the duodenum. If we view the lumbar wall as the lower base of support of the inferior abdominal viscera, which it really is in the recumbent position, it is interesting and important to note that it consists of two broad lateral hollows, separated by a prominent ridge of osseous structures, the bodies of the lumbar vertebræ.

PROTECTION AFFORDED THE ABDOMINAL CONTENTS BY THE COSTAL WALLS.

The subdiaphragmatic contents of the abdomen are most effectually protected by the arched domes of the thoracic wings.

It is important to remember that the apex of the diaphragm on the left side rises as high as the sixth intercostal space, or about one inch below the nipple line, and on the right side to a point about one inch lower, and that posteriorly its summit is nearly on a level with the ninth in-

tercostal space. It is therefore apparent that the stomach in the empty state with the liver, spleen and gall-bladder are so sheltered by the lower segment of the thorax that when they are exposed to direct violence its primary impact is first encountered by the ensiform and the costal cartilages, the ribs, pleura and lung.

By this provision in the architecture of the economy, while the pulmonary organs are most exposed, those solid viscera lying under the diaphragm are spared. Hence why we will so often see costal fracture below the sixth intercostal space, with or without pleural or pulmonary complications, when the abdominal contents entirely escape.

The general muscular support of the abdomen is quite equally distributed, and protection is only defective at those points through which the umbilical vessels passed in fœtal life; and over the inguinal and crural planes are rendered defective through the evolution of anatomical development.

MUSCULAR WALL OF ABDOMEN.

The muscles investing the antero-lateral walls of the abdomen are strengthened, enveloped and anchored by powerful fibrous sheaths and a broad, strong tendinous aponeurosis. The muscles are so arranged that they pass downward from the thorax in the center and obliquely laterally.

In the male the abdominal cavity is wholly enveloped by muscles, except in the median line above the umbilicus, where the fibers of the recti diverge. Below the navel in females who have borne many children the internal borders of the recti at the linea alba are so widely separated that support is only maintained by the central aponeurosis. The principal central support of the abdomen is derived from the recti muscles. Each of these muscles is separated from the other by a dense fibrous septum and is enveloped by an investment of the abdominal fascia, which splits in two as it approaches its outer border, and then coalesces as it approaches the linea alba.

Thus the sheath of the abdominal rectus is more powerful and resistant for the volume of the muscle than any other met within the body. The action of the rectus abdominalis when the body is fixed is to actively compress the abdominal viscera (*a*) backward, (*b*) upward, (*c*) downward and (*d*) partly laterally.

When the muscles of the lateral walls act conjointly in contraction, the extent of intra-abdominal displacement is very great, in fact practically pushing the movable viscera up under the diaphragm, downward into the pelvis and backward along the lateral hollows of the spine.

We sometimes see individuals with such command over their abdominal muscles that they can flatten and depress the ventral convexity at will. If we observe the motions of the thorax while this ventral feat is being performed, it will always be noticed that abdominal collapse is simultaneous with a forced and prolonged expiratory act, the lungs rising high under the clavicles while the viscera follow upward the retreating diaphragm.

The oblique and transverse muscles, besides supporting and protecting the abdominal contents when the body is fixed, are capable of maintaining remarkable pressure on them. They are invested externally by a dense fascia, which above is continuous with the thoracic, below blends with Poupart's ligament, laterally with the lumbar fascia and with the linea alba. The coalescence of the external fascia abdominalis with the upper margin of Poupart's ligament is what produces that crease in fat people which runs across the lower side of the abdomen.

It has recently been claimed by a distinguished writer on anatomy that this depressed seam does not correspond with Poupart's ligament and is an unsafe guide in operations; that the ligament may be much lower than it, and the only safe guide to the ligament is by a line drawn from the anterior subspine of the ilium to the pubic symphisis.* But this is clearly an error and capable of misleading one not accustomed to manipulations on the living anatomy. Poupart's ligament rarely deviates in its course, and in all cases the under layer of the integument is more or less adherent to it.

The femoral arcade marks the inferior boundary of the three lateral muscles of the abdominal wall, and passing through their tendinous insertions is the inguinal canal, a portal which, when normally formed by augmentation of abdominal pressure instead of being opened, is all the more compactly closed. The psoas

*Keen in American edition of "Gray's Anatomy."

muscles on the inside, the quadratus lumborum and erector spinæ inclosed in laminæ of the lumbar fascia, covering the loin, form the posterior muscular boundary of the abdomen.

The abdominal wall is everywhere lined by a strong fibro-cellular membrane, designated variously according to the situation it occupies. Thus we have the fascia transversalis continuous with the pelvic fascia, the iliac and inner lamella of the lumbar fascia.

THE ABDOMINAL CAVITY.

This cavity possesses several distinctive characteristics.

1st. It is the least protected by an osseous envelope.

2d. Its serous membrane is of vast dimensions.

3d. It contains important viscera outside of its serous investment.

4th. It is ever varying in capacity.

Though apparently the most exposed to violence, by a moderate inclination of the trunk on the hips and a firm contraction of its overlying muscles, force is received and diverted on other less vulnerable parts; and thus its contents may escape serious damage.

CONTENTS OF THE ABDOMINAL CAVITY.

Exclusive of the renal organs, all of the abdominal viscera are more or less completely invested by the peritoneum.

The greater part of the cavity of the peritoneum is occupied by a hollow tubular structure, the alimentary canal, the greater part of which is tethered to the spine by the mesentery. This convoluted tube is constantly distended by air and by gases, elaborated in the chemical processes of food assimilation. The gaseous distention of the intestines floats them in a serous liquid of the peritoneal sac. With the pneumatic organs above, they aid in giving buoyancy to the whole body. In the event of contusion or sudden abdominal compression, these gaseous coils, by their mobility and resistance, serve to diminish and minimize its effects.

In the normal state, all the abdominal organs are in incessant motion. This is attributable chiefly to two influences: first, to respiration; secondly, to the small intestine, from pylorus to the ileo-cæcal portal, which by a continuous vermicular motion, called peristalsis, is in ever-ceaseless action, varying according to changing physiological conditions. The circulation of the blood must constitute another factor to intra-peritoneal motion by the powerful impulse transmitted by the aortic torrent, the steady upward current through the cava, the confluent tide through the large portal tributaries, and lastly the pulsation of those large arterial trunks leading to the great centers of digestion. The coils of the jejunum and ilium lie in close contact with the anterior and lateral abdominal walls, being separated only by the omentum and probably a very thin medium of lymph. The stomach when distended with food descends down as far as the umbilicus, lying rather to the left of the median line in nearly a vertical position.

The large intestine in its ascending and descending segment lies so far back as to be well protected. The caput coli in the right iliac fossa and the sigmoid flexure in the left are more exposed. The bladder, empty, is safely sheltered by the pubes, but when distended it rises into the abdomen, its anterior surface passing against the parietal peritoneum, while its fundus is inclined toward the sacrum.

The pregnant uterus rises up into the abdominal cavity after the fourth month. It is apparent from the foregoing that the arrangement of the abdominal viscera is ever undergoing changes under various physiological conditions and various circumstances in health, and it is well to remember that all these organs, under the vitalizing influences of life, are like so many independent beings in motion, their relation then and after death bearing but little analogy. Nor should it be forgotten that assymetry of development in the organs, variability in origin and direction, with altered relations of structure, are exceedingly common in the abdomen.

The serous membrane, investing the abdominal sac and its contained organs, is variously described by different anatomists, although their descriptions are usually so complex and intricate that nobody can clearly comprehend them. To briefly and accurately describe it in a few words stripped of superfluous verbiage, it may be said that it is quite identical to the synovial membrane of an articulation; that the peritoneal cavity is simply a joint in which move and play on each other the

organs of digestion. This joint is first invested with a parietal layer, and next all the contained organs are covered more or less by the same structure; except where they are attached.

It is a lymph sac, and its fluid, secreted, serves the purpose of a lubricant. Its structural study has been vastly complicated by that apron of tissue known as the omentum, the real purpose of which is yet unknown. But in this connection, what most concerns us is an acquaintance with the functions of the peritoneum.

In the average text-book on physiology, but little information is imparted on the vital properties of the peritoneum. It is important, however, that we become acquainted with some of these before its traumatisms are considered. In examining the contents of the peritoneum, we will notice that the ganglia of the solar plexus, the center of the great sympathetic system which provides the nerve supply of all the abdominal viscera, is lodged in duplications of this serous membrane, and that it is placed behind the stomach, in front of the aorta and the crura of the diaphragm. This vast plexus we will find receives the splanchnic nerves and branches from the pneumogastric. As its filaments spread over the viscera a separate plexus in various directions is formed and designated according to locality. This system presides over vegetable life and is concerned almost exclusively in the processes of digestion and nutrition, in metabolic and regenerative changes. This we can often demonstrate in inguinal colotomy, and in other instances when on division of it with the scalpel no pain is felt. But the basement membrane of the peritoneum of fibro-cellular tissue with the advent of inflammation becomes exquisitely sensitive. The peritoneal cavity has only an imaginary existence, for all the surfaces of the viscera within it lie in close contact; contraction and relaxation of the abdominal muscles regulating the extent of intestinal distention in health and confining the viscera in close apposition. As has been stated, normally all the organs invested by the peritoneum are in constant motion, but with the advent of inflammatory changes in its textures, as this extends into the muscular and glandular coats of the intestine peristalsis diminishes or ceases, and the secretory action of the glands or follicles is for the time reduced or wholly arrested. The bladder wall, as inflammatory processes are propagated into its tunics or the overlying expulsive muscles of the abdomen, is unable to contract and expel the urine. The peritoneum possesses marvelous plastic properties, so that on the slightest irritation being applied to any part of its surface it at once becomes adherent to the nearest organ.

Another salutary property of this great lymph sac is its remarkable facility to absorb fluids.

Moderate quantities of healthy urine, bile, chyle, pancreatic, gastric or intestinal juice or blood, are promptly resorbed by it without dangerous inflammation supervening. Enormous effusions of blood into the cavity of the peritoneum are quickly disintegrated and resorbed. It is equally competent to dissipate and take up the serous elements of local inflammatory action, and my experience has convinced me that it is equally potent in walling off, reducing, destroying and resorbing small foci of suppurative formation.

The abdominal viscera being abundantly provided with a vascular supply in the event of sudden commotion, are frequently the seat of hemorrhagic effusions. This may occur into the parenchyma of a solid organ through the vessels of the mucosum of the intestine, into the lumen through the capsule of an organ, extra or intra peritoneally. The kidney, of all the organs of the abdomen, the most frequently is the source of traumatic hemorrhage.

The blood may escape through its capsule into the loose retro-peritoneal tissues within the capsule or into the hilum and escape through the ureter. In occasional instances those types of hemorrhage may coexist. They are most frequently encountered in association with spinal injuries, though they do exist independently of cord implication, as a case demonstrates now in my service (July 23, 1894).

DYNAMICS OR PHYSICS OF THE ABDOMEN.

The abdomen provides the largest cavity in the body, which may be regarded as the laboratory of digestion, the center of never-ceasing chemical and vital changes. Its contained intestinal tube bears a striking analogy to the "worm" of a still, the only essential mechanical difference being

that the concentrated nutritive elements are taken up from its walls by vascular absorbents which collect and deliver them to the general circulation. The contents of the abdomen, as we have seen, are so effectually protected from behind that damage to its contents from this direction is rarely possible, however applied. Its broad muscular apron, its antero-lateral areas, are capable of offering great resistance to force when notice of it is given.

The hollow viscera of the alimentary canal containing semi-solid fluid and gaseous elements, its anterior central surface emits a tympanitic note on percussion, and is therefore capable of considerable compression when this is applied gradually. Compressed from one side or the other, the contents of the abdomen meet with but moderate resistance against the muscular parieties. In compression applied over its dorsal wall resistance is quite absolute and complete.

Force applied directly from before encounters but a limited resistance from the recti or oblique muscles, and passes inward until it is suddenly arrested by the vertebral bodies or by the sharp edge of the promontory of the sacrum. The summit of the abdominal cavity, that part immediately under the diaphragm, is most effectually sheltered by two pneumatic buffers, which so protect the organs in the epigastrium that their osseous braces, as a rule, fracture, and the lung with its serous investment suffers, while the abdominal viscera generally escape.

[TO BE CONTINUED.]

THE GENERAL PRACTITIONER'S KNOWLEDGE AND RESPONSIBILITY IN GYNECOLOGICAL TROUBLES.

JOSEPH PRICE, A.M., M.D., PHILADELPHIA.

The gynecological specialist is the wonder of the medical nineteenth century. He is a thing apart, often made to order, and needs alcohol and glass to preserve him from the attacks of those who refuse to acknowledge him as the grand receptacle of all truths relative to women and their diseases. Where does he come from; what does he do; how does he do it and, most important of all, does he know how to do it?

The refined specialist comes from the ranks of the profession. It is not given any man to leap, ready-armed to combat any special disease, out of the arms of his collegiate alma mater medicinæ. Medical colleges give us the generalities of the science, not the specialties. True enough, we are now given a glimpse into the promised land of this or that branch of surgery or therapeutics from the standpoint of specialties, but it is as Moses gazed into that wished for country, and not as its possessor, that such knowledge is doled out. The general practitioner is a most maligned, long-suffering delver in the dross of disease, receiving little credit for his work, attainments and experience from most of those who ride above him on the fiery clouds of their own imagination. This is especially true of the made-to-order specialist, who, having no general knowledge or experience, does not see the need of it and therefore is not able to appreciate the man who has it. Many men can see no further than their own attainments nor reach into the field of others. This is especially true in the lines of many so-called specialists. What connection, they will ask, is there between this or that disease and the specialty in which I am engaged?

The whole truth is that there is just as much connection between a well-balanced knowledge of all disease and any specialty as there is a general relationship of all diseases of the economy, knowledge of which renders a man a fit practitioner of medicine. What would we say of a medical school whose professor of the practice of medicine lectured upon all diseases save that of the liver, because in his experience he had found hepatic troubles rare, or omitted brain diseases on account of the scarcity of the article, and so on through the category? In medicine and surgery we must put it down as in the exact sciences that no

knowledge comes amiss, that every fact and scientific observation is a clew or a key or a step toward some other fact, developed or latent, and that hence a general knowledge, or set, or series of facts are levers furnishing a fulcrum, or power, or place to stand upon for the digging out of new facts and making progress. Remembering all this, it is not easy to endure the opprobrium heaped upon the general practitioner, as a "hayseed," a "back number," a "mossback," a "far-away Moses" and the like. His experience is the foundation that all specialties are built upon; his knowledge is the basis of all refinement in the line of special work; his observations were the only foundations of the first specialists.

Who were the first specialists, I beg to inquire? Go over them on your fingers and see from whence their knowledge and skill of sterling rarity. How many of us to-day are on a par with them? Which of us can equal in a general diagnosis our Agnew or McGuire or Gross? And so on through the list. By whom were the early records of gynecology made? Who knows the plodding of McDowell, of the country practitioner Baynham? Who will say these men did not think and look and learn from their general work to reach out and successfully lay the foundations for all that is now received as the refined work of the best specialists? These men were types of all the pioneers in the line of accepted special work. Their knowledge was wide and varied. They were thinking men, taking nothing for granted because there was nothing to accept; thinking out their rules, testing them by reason and general experience and bringing them down to a special application.

How different all this is in the ready-made specialists. This one comes out an oculist without having seen or treated a score of cases on his own merits. That one an obstetrician, mayhap a professor, with a dozen or so cases to his credit. The successful removal of corns requires greater experience than this.

The general practitioner is, perforce of his relation to the family, bound to give much of his time and attention to the diseases of women and children. It must be remembered that women and children furnish the bulk of the work of the general practitioner, and hence his knowledge of these must be more than ordinary. To obstetrics his attention is necessarily drawn and consequently to the many problems and perplexities connected with it. If he is a careful man he must be an authority on the complications and their relation to many of the after-complaints of women and to their force as a causation of real disease. Hence it is that the general practitioner is likely to be good authority on many of the diseases of women, and particularly as to the presence of pathological conditions. Not that he is necessarily able to give positive surgical assistance in cases falling under his notice, but he is able to diagnose the presence of lesions requiring such interference.

Displacements of the uterus he at once recognizes and reduces. Or, finding the latter cannot be accomplished, he knows that adhesions have probably done their work, and he appreciates the necessity of more than ordinary treatment, because his own efforts have been futile.

He knows immediately, as Dunlap once so wittily said, that something is wrong because something is present which is not found in the anatomy. Observations and investigations must go hand in hand with previous exact knowledge. In all diagnosis what is should be weighed with what ought to be and the balance struck accordingly. Facts are facts. When we know the relatively normal conditions it is more or less easy to discover the abnormal. To the careful physician of long experience much that is written and talked these days about the value of this or that proceeding, the really ultra-refinements of presumed cleanliness will appear ridiculous. It is for him to sift each and every suggestion, to weigh it in the balance of positive experience and decide accordingly. If there is an atom of value in a suggestion, to get it out, appropriate it and make it useful is the way to make the foolishness of fools the wisdom of wise men.

Much of the work of gynecology to-day would be useless, or rather not needed, if every obstetrician were as careful as he should be in the handling of women coming under his care. A woman after parturition must neither be treated into disease nor be left in a condition to produce it.

Carelessness in the handling of women after miscarriage is a serious failing of many physicians. Broadly speaking, every woman after a miscarriage should have

the same careful attention as after confinement. She should rest, if anything, longer because the processes of labor are natural, those of abortion unnatural. In labor the placenta is most apt to come away entire, while in miscarriage it is prone to cling and give trouble. Retained placenta is the fruitful source of much of the trouble necessitating after-operation upon the pelvic organs, and is a prolific cause of subsequent menstrual derangement due to subinvolution, congestions, displacements and the like.

As to curetting in these cases, the rule for each individual case cannot be absolutely laid down. Generally speaking, it is best to avoid curetting if the discharges are not offensive, if the bleeding is only moderate and does not come on in gushes, and if there are no other indications, such as continued crampy pains after miscarriage. I do not often find it necessary to curette a uterus, but when I do I never make internal applications of carbolic acid or any other of the so-called stand-bys. I have come to consider all this as meddlesome surgery and do not sanction it. This position, bear in mind, is not a dogmatic assertion drawn from a small experience in such cases, nor is it due to a lack of observation of cases other than my own treated by escharotics, caustics and disinfectants. My opinion is a conclusion reached after a careful weighing of my own and others' experience.

Post-partum douches I consider as a safeguard rather than a necessity. Do not misunderstand me. In all this discussion we must reason together. Among you are men who have never seen a case of childbed fever in an experience of ten years, and whose routine treatment has been simple care and cleanliness without using a syringe. Others, no doubt, have seen an occasional case whose origin is now as much a mystery to them as is the origin of species. With such different experiences, opinions must vary as to the value of douching before and after labor. One view I have heard, and agree with in its philosophy, says: "If we are clean when we start and stay clean while we work, we will be clean when we stop." A post-partum douche is unnecessary. Unfortunately we do not all know how to be clean or to stay clean, and so ending clean may be uncertain. So to avoid risk the post-partum douche comes in as a prophylactic. The ante-partum douche is valuable to insure the cleansing of the parturient passages and saves possible infection of the eyes of the child. For this reason I advise the ante-partum douche. I know its value. The hot—moderately so—post-partum douche keeps us longer at the bedside of the mother, assists in the contraction of the uterus, and so is a safeguard against that awful complication of labor, post-partum hemorrhage, which I firmly believe should never occur. The douches should be mild and given carefully.

We naturally come to the consideration of the injuries to the mother, to wit, uterine and perineal tears. Injuries to the bladder are no longer frequent, thanks to the more general understanding of the forces of labor and the use of the axis-traction principle in the manipulation of the forceps. The old see-saw method of delivering women with the forceps, with a pull and a tug, with no other idea than to tear something away from her pelvis, is happily going out of fashion; not altogether gone, but going. Let me urge upon you the value of the axis-traction forceps, and at the same time I advise you to study carefully the advantages it gives us in the delivery of a woman, both for her own safety and that of the child. The subject cannot be here entered upon in detail, but I shall be happy to discuss it with you and to answer all queries on the subject.

Perineal tears are the commonest injuries met with, and are most likely to give both the doctor and his patient a deal of after-trouble. If not repaired, the woman is for a long time uncomfortable, and oftentimes her discomfort goes on to positive harm and renders her useless as an active member of the household. If the tear is through the sphincter, the filthiness of the condition is almost as bad as death itself to the cleanly woman. If the tear is but fascial, the drag and displacement of the uterus and bladder often produce most serious complications. A woman with her uterus sinking down between her thighs, or resting at the introitus vaginæ, is an object for the keenest commiseration. All this can be avoided by the early mending of the tears.

As a general rule cervical tears require special consideration. They should be stitched if relatively extensive, but it is to

be remembered that the simple contraction of the uterus often reduces what seems a serious laceration to one of comparatively small importance. Tears of the perineum ought to be mended as early as possible; not later than six or eight hours after the occurrence. This is true for two reasons: First, because they are more likely to heal, and, second, because a secondary or late operation taxes the patient with what seems an additional operation when the parts are more tender.

Again, if ether has been administered during the delivery, early operation makes a second administration of the anesthetic unnecessary, and this means a great deal to the patient. The suture material may be either silk or silkworm gut, preferably the latter. The ordinary short sewing-needle is all that is required, although the Emmet needle is better. The tear should be stitched up as any other wound, and should not embrace in the suture parts not injured. For this reason the old method of stitching from the outside when the tear is inside is all wrong. Tears in the vagina occur from the inside outward, and the stitching should be done in the same direction. If the tear extends into the bowel through the sphincter, it should be stitched carefully, as I shall demonstrate to you, to close the bowel. The ends of the sphincter muscle should be exposed and united, as I shall make plain. The so-called flap-splitting operations are to my mind not scientific in conception, and I believe the final verdict will be that they cannot stand the test of time. Too much care cannot be taken to not include too much tissue in any suture. When this is done strangulation necessarily takes place and of itself defeats union. By the inside vaginal sutures a deep vaginal bevel is produced and the parts are brought into their moral physiological relation, as may be seen on examination, for the anterior and posterior vaginal walls are in apposition.

The recognition of pelvic inflammatory conditions requires careful bimanual examination. The history of the case will help us out if thoroughly obtained, and the factors in all pelvic disease must constantly be held in mind. The gonorrhœal origin of much pelvic disease must not be forgotten nor underestimated. The history of difficult labors with succeeding inflammatory attacks, of miscarriages or abortions, must never be forgotten. As an inestimable factor in diagnosis, the bimanual examination must not be overlooked. It would be folly to expect to discover neoplasms, ovarian or inflammatory, if the normal relation, position and general contents of the pelvic basin are not thoroughly understood and distinguishable by examination. No careful general practitioner should lose opportunity to discover and map out all that is to be known of these. This being done, what is abnormal can generally be readily appreciated.

The history of ectopic pregnancy, its importance and frequent fatality, make it incumbent on all to study this subject carefully; especially to hold in mind the salient features of this condition. A long period of sterility, then disappearance of the menses followed by a stroke of shock and pain, with subsequent bleeding kept up for an indefinite period—these signs make the case suspicious. In every such case take every precaution to arrive at a correct conclusion.

Dermoid cysts often are at the bottom of much serious trouble in women, and are to be suspected in the presence of much and long-continued pain without other assignable cause. Suppurating dermoids are a prolific source of peritonitis and tumors; their position and size, with fluctuation and firmness combined, may lead us to suspect their existence.

Fibroid tumors and their removal is no longer a question of expediency. The operation is settled and is as safe as any other in surgery. The only question is when the tumor itself and when the ovary should be removed. In general terms the ovaries ought to be removed by election if the tumor is small and the woman is under forty years of age. After this period ovariotomy is of doubtful expediency and the tumor itself should be the operation of election.

You will see that in this paper I have tried rather to offer general advice than to go into a detailed description of any operation in particular. Special surgery requires special study, and the real specialist is the one who is ready to give the subject this time and study. But there are emergencies when every man must act by himself, and my object here is to suggest guiding points—how to proceed, where to stop. Otherwise the subject is too broad for an incidental society consideration.

COMMUNICATIONS.

THYROIDECTOMY IN THE TREATMENT OF GOITRE.

JOHN B. ROBERTS, M.D., PHILADELPHIA.

My object in bringing this topic before you is to call attention to the ease with which the enlarged thyroid gland can be enucleated and the mechanical symptoms caused by its pressure removed. After medicinal treatment has been employed sufficiently long to make it evident that no important change in size is to be expected, it seems to me that thyroidectomy need not be delayed.

Perhaps two months is as long as one need wait if during that time the approved remedies have been employed in full doses. It must be remembered that goitres not infrequently vary in bulk without relation to medicinal treatment; hence a diminution is not necessarily the result of the local or internal medication. If dyspnœa due to pressure on the trachea is marked, or if hoarseness from compression of the recurrent laryngeal nerves is present, one month's unsuccessful treatment by medicines would probably induce me to operate.

Parenchymatous injections of alcohol, tincture of iodine, or other irritants do not seem sufficiently successful or free from danger to be adopted as a routine, though cases may still come under my care in which I shall be willing to try them. Tapping or incision and packing of cystic goitre are available; but after the former the cyst is liable to refill, and the latter operation makes almost as much scar as, and is not much less serious than, thyroidectomy. Electrolysis does not seem to have given sufficiently certain results to make it attractive. Tracheotomy may be demanded when tracheal compression is marked, though in some cases subcutaneous or open division of the deep cervical fascia to allow the bronchocele to bulge forward will avert the threatened suffocation.

Division of the thyroid isthmus to lessen pressure, or ligation of the thyroid arteries to cause atrophy or prevent increased growth, are operations almost, if not quite, as serious as removal of a portion of the diseased gland.

I now speak only of thyroidectomy, or removal of a portion of the thyroid gland. Total extirpation is unwarranted, because the occurrence of myxœdema as a result of the entire loss of the thyroid gland is pretty well established, experimentally and clinically. The most disfiguring and most compressing part of the goitre may be removed, and a portion of one lobe left to carry on the function of the gland. I would do this even if the part left was apparently not healthy to the naked eye. It seems pretty well established that a small portion of the gland, or a small accessory gland, if such be present, is sufficient to avert the occurrence of myxœdema in patients subjected to removal of goitrous masses.

Thyroid feeding, the administration of thyroid extract, or the implantation of the thyroid gland of one of the lower animals, in the connective tissue or the peritoneal cavity of patients previously subjected to extirpation of the gland, may overcome the tendency to myxœdema; but until this is really proved the surgeon should do only a thyroidectomy, and leave a portion of the gland in position.

I shall not go over the steps of the operation in detail, as they are sufficiently clear to any operator who is prepared to deal with sharp hemorrhage and who is careful enough to avoid injuring the recurrent laryngeal nerves. A vertical incision is made in the median line of the neck or above the most prominent part of the tumor, and the necessary portion of the fibroid, cystic or hypertrophic gland enucleated. Perfect asepsis or antisepsis is essential.

The enlarged thyroid in exophthalmic goitre has been subjected to operation, but the general character of this affection would deter me from operating upon the bronchocele, which is only one symptom of the disease; unless further statistics show its value in an unmistakable manner.

I add the reports of two cases to illustrate the subject. Neither goitre was of great size, but both were annoying to the

patients. They were radically cured by operation. The enormous fibroid goitres seen especially in Europe would, of course, be more difficult to deal with, especially in regard to the control of bleeding.

CASE I.—Single woman, aged twenty-one, with a family history of phthisis; first noticed enlargement of the thyroid gland when she began to menstruate, at the age of thirteen. The enlargement rapidly increased for three years, when it began to press upon the trachea to such an extent that respiration was interfered with, and she was obliged to give up going to school because of the dyspnœa that occurred while walking. After the lapse of a year the bronchocele began to diminish in size, but for the past three or four years had not changed much in bulk.

The patient had been under medical treatment for some time for the thyroid enlargement, without diminution in the growth; and I therefore determined, in April, 1891, to excise the most prominent portion of the gland. A four-inch incision was accordingly made in the median line of the neck over the most prominent portion of the enlargement. The middle lobe or isthmus of the gland was first enucleated, and I subsequently removed the entire right lobe. In the removal the sheath of the common carotid artery, with the descending branch of the ninth nerve upon it, was clearly exposed to view. A portion of the left lobe of the gland was then enucleated, making the size of the mass removed about that of a closed fist. The arteries requiring ligation were quite large and numerous. Sublimate gauze dressing was applied with considerable pressure in order to avoid oozing.

About half an hour after the operation the patient became so cyanotic from the pressure that the dressing, which had become saturated with blood, was removed. Her pulse became rapid and weak, but the removal of the dressing, the application of hot water, the administration of digitalis and other restoratives were followed by cessation of bleeding and quick reaction. A clean dressing was immediately applied. The next day the patient was in good condition with normal temperature. The wound healed promptly without suppuration or marked swelling. The patient was sent to the seashore about three weeks after operation with the wound healed, though her voice was quite husky. This was probably due to interference at the time of operation with the recurrent laryngeal nerve.

The woman has been seen repeatedly since operation, the last time being nearly three years from the date of the thyroidectomy. Her health has continued good; her voice has recovered its normal quality, and there is no evidence whatever of myxœdema. It was because of the fear that myxœdema might occur that I allowed a portion of the left lobe of the enlarged gland to remain. The goitre seemed to be of the ordinary hypertrophic variety, though no microscopic examination was made. The contour of the neck is now almost perfect, except for the unimportant scar; and there has been no further growth in the portion of the gland allowed to remain.

CASE II.—A young man, seventeen years of age, had noticed two years previously a small swelling in the front of his throat, about an inch and a half to the right and some distance below the Adam's apple. The tumor was not painful, but steadily increased in size until at the time he came under my observation there was some interference with respiration. He came to Philadelphia for the purpose of having the growth removed a year ago, but the surgeon who examined him advised against operative interference. When I first saw him, in November, 1892, the patient was the subject of a well-marked goitre. The girth of his neck over the most prominent part of the tumor was 15¾ inches. The enlargement involved both lobes of the thyroid gland, but the right was larger than the left. Stridulous respiration was marked, even when he was perfectly quiet and not taking any exercise. Breathing became easier as soon as the growth on the right side was pushed away from the trachea. This phenomenon I repeatedly tested, and it was very marked. Above the main mass on each side was a small nodule, somewhat separated from the rest of the tumor, but evidently being the upper portion of the lobe on the corresponding side. There was a well-marked groove between the two lobes, showing little involvement of the isthmus, and a furrow between the upper nodule and the main mass on each side. There was no exophthalmus, but there existed a doubtful systolic murmur. I treated the patient for some weeks with digitalis and quinine, with ointment of

the red iodide of mercury and lanoline externally, and subsequently with fluid extract of ergot.

After a month's treatment I determined to remove the prominent portion of the gland, which was making pressure upon the trachea. The patient took ether rather badly, as was to be expected from the interference with the respiration due to the growth. The right lobe of the tumor was exposed and was found to be cystic. The cyst was opened, and about an ounce and a half of dark-brown fluid was evacuated. The small nodule above and the right lobe containing the cyst were dissected from the underlying structures. The sheath of the carotid artery was exposed, and the lower portion of the mass extended close to the sheath of the subclavian artery.

Stridor was apparent after the operation, and some dyspnœa remained, which was, however, relieved to a considerable extent by loosening the bandage. Four days later the dressing was removed. Union by first intention seemed to have taken place. A dressing of gauze and collodion was applied, and on the sixth day after operation the patient was allowed to get up. Four days later a slight hemorrhage occurred through the gauze and collodion dressing as the result of a fit of coughing. Slight oozing took place for a couple of weeks through the opening made by the giving way of the union at this time. The blood-clot contained in the cavity left by the excision of the right lobe of the gland did not break down into pus, but gradually became organized. The patient's temperature was normal during nearly the whole of the convalescence, though at one time shortly after the operation it rose to 101°. The patient was discharged about five weeks after the operation. His breathing had become normal and the appearance of his neck was greatly improved, though there was still, of course, enlargement of the left lobe. There was no hoarseness remaining as the result of the operation, as in the former case.

A year later the patient wrote to me that he had had no trouble in breathing, that his voice was normal, and that there was no change in the appearance of his neck. The operation, therefore, was in every way satisfactory.

A REPORT OF FOUR CASES OF DIPHTHERIA TREATED BY ANTITOXINE.

GEORGE A. MUEHLECK, M.D., PHILADELPHIA.

The employment of pure cultures of pathogenic microörganisms and their toxic products for purposes of immunization, as well as for combating certain infectious diseases, is comparatively of recent date. The history of the labors of Pasteur, Koch, Kitasato, and others in this field has become common property for the entire medical world, so that a mention of them here would be superfluous; but their work has opened up new avenues of investigation and research which have already yielded practical results, as it seems, of the most far-reaching consequence, and a promise of still greater achievements in the future. I refer here especially to the work of Behring, Ehrlich, Brieger, Wernecke, Boer, Schuetz, Kitasato, Wassermann, Kossel, Aronson, and others in Germany, Roux and Yersin in France, and Tizzoni in Italy, as a result of which the doctrine of immunization against certain infectious diseases has been further elucidated and experimentally confirmed on animals at least. Behring and his colaborer were the first to show that the blood or milk of animals so immunized has the power when ejected hypodermatically, or into the peritoneal cavity, to immunize other animals or to protect them from the consequences of inoculation of virulent cultures of pathogenic microorganisms or intoxication by the products of the same species with which the first animal was made refractory. In other words, the milk and blood-serum have developed antitoxic properties which have the power to neutralize the toxic action of the virulent cultures and their products. This neutralization of the toxic by the antitoxic principle takes place even outside of the animal economy when mixed

in a test-tube in obedience to the laws of proportion (Behring, "Gesamte Abhandlungen ueber Disinfection, Immunisirung, Blutserumtherapie"). Animals which have been made ill by the injection of fatal doses of virulent cultures of their filtrates are restored to health if a sufficient quantity of antitoxic serum be injected within a stated time (Behring, "Blutserumtherapie und die Immunisirungsmethoden zum Zwecke der Gewinnung des Heilserums," 1892). Of the infectious diseases which have been the subjects of this line of investigation, and in which the results have been most encouraging, tetanus and diphtheria, and, to some extent, streptococcus infection, are preëminently to be mentioned. Of these, however, only diphtheria is relevant to this paper; but the principles involved are the same in all. Behring's method of securing antitoxic serum of diphtheria for therapeutic purposes is similar to that now generally accepted by all investigators—that is, by injecting hypodermatically into an animal gradually increased doses of attenuated dead cultures of Klebs-Loeffler in order to effect a certain degree of basal immunity. Subsequently this basal immunity is intensified by injecting increased quantities of living and virulent cultures.

This method is based upon the fact already established by the investigations of Koch and Katasato, viz., that specific toxine and antitoxine neutralize each other immediately outside of the living organism when mixed in the test-tube in obedience to the law of proportion. Formerly toxine and antitoxine were injected separately, but owing to variations for absorption exact results could not be obtained. Now they are injected together. For the practical application of the method it is best to use a test-toxine, the immunizing power of which has been tested and which is derived from more mature bouillon culture, to which has been added ½ per cent. of phenol. Of the solution used by Behring and his co-laborers as a test poison, 0.3 c.c. represents the minimal fatal dose of 1,000 gms. body-weight; 0.8 c.c. of this solution is injected into an animal weighing 200 to 300 gms., together with the substances to be tested for the antitoxic power in decreasing proportions.

For example, 0.4 c.c., 0.3 c.c., 0.2 c.c., etc. The result can be determined approximately in twenty-four hours, and with accuracy in forty-eight hours, by the presence or absence of local œdema; provided that the proportions of the material to be treated for the antitoxic power have been properly measured. The quantity necessary to neutralize 0.8 of this test-toxine will vary according to the amount of antitoxine present. These injections are made *seriatim*, and always give absolutely reliable results. As a final result of their labors these investigators have animals of whose serum 1½ mlgms., or of whose milk 0.075 mlgm., are sufficient to neutralize 0.8 c.c. of this normal toxic solution. A serum is said by Behring to represent 1 antitoxine normal if 1.0 c.c.: 100 body-weight is sufficient to neutralize 0.8 c.c. of this normal toxic solution—that is, if 0.8 c.c. of this toxic solution is injected into a medium-sized guinea-pig (about 500) it will remain well if normal antitoxic serum in the proportion of 1:100 body-weight (about 5 c.c.) had been injected one-quarter hour previously (Behring, "Gesamte Abhandlungen," etc., ii, p. 323). In this manner serum has been obtained representing sixty and more antitoxine normals (Kossel and Wassermann, *Deutsche med. Wochenschrift*, 1894, No. 16, "Ueber Gewinnung und Verwendung des Diphtheritschen Heilserums") in Koch's Institute, Berlin.

Roux, who began his experiments in 1891, uses for purposes of immunization a test poison, 0.1 c.c. of which will kill a guinea-pig of 500 gms. in twenty-four to forty-eight hours. His test poison is accentuated with a solution of iodine (liq. de gram.). He gradually increases the dose by diminishing the proportion of iodine. After several weeks it is given pure. In this way very powerful antitoxic serum, with an immunizing power of 1:50,000, is obtained—that is, a guinea-pig will resist 0.1 c.c. of recent virulent cultures if serum in proportion of 1:50,000 body-weight is injected (*Annales de l'Institut Pasteur*, No. 9, September, 1894).

Since the beginning of the year 1894 antitoxic serum has been extensively used in cases of diphtheria in the hospitals of Berlin and Paris. Henoch, Heubner, Koch, Kossel and others testify to its absolute harmlessness even in doses of 90 c.c. In no instance was any irritation of the kidneys or any unfavorable influence on the general health observed

(Behring, "Gesamte Abhandlungen Disinfection," "Disinfection, Immunisirung, Blutserumtherapie"). In six Berlin hospitals 220 cases were treated, with 76.4 per cent. of recoveries. Among these were 67 tracheotomies, with 37 recoveries —that is, 51.1 per cent. The beneficial effect of the treatment was most apparent the earlier it was begun. Of 6 treated the first day, all recovered—that is, 100 per cent.; of 66 treated the second day, 64 recovered—that is, 97 per cent.; of 29 treated the third day, 25 recovered—that is, 86 per cent.; of 39 treated on the fourth day, 30 recovered—that is, 77 per cent.; and of 23 treated on the fifth day, 13 recovered —that is, 56 per cent. (*Deutsche med. Wochenschrift*, Nos. 22, 23 and 24, 1894; *Berlin klin. Wochenschrift*, 1894, No. 29).

Roux, in Paris, reports a mortality of 24 per cent. in the Maternité, while the mortality in the hospital of Trosseau, where no serum was used, was 60 per cent. during the same epidemic. Owing to the fact that the quantity of serum available in this country has hitherto been very limited, a report of the following four cases treated by this method may be of interest.

Case I.—H. C., five years old, male, was taken ill on October 18th.

Status præsens. Mucous membrane over tonsils and posterior pharynx red and congested; small spots visible over tonsils; breathing somewhat labored; cervical glands swollen; pulse, 108—strong and regular; temperature, 100⅘°; respiration, 24.

October 19th, A.M. General condition about the same; membranes have extended; breathing more difficult; temperature, 100⅘°; pulse, 108; respiration, 24. At 8.30 P.M. injection of 1 c.c. of antitoxine —Schering—near scapula.

20th, A.M. General condition much improved; temperature, 99°; respiration, 24; breathing very much easier. P.M. Condition not so favorable; breathing very difficult; retraction of epigastrium and supra-clavicular spaces during respiration; face somewhat cyanosed; pulse, 130; respiration, 24; temperature, 100°. Intubation or tracheotomy seems indicated. At 8.30, second injection of 1 c.c. antitoxine —Schering—near scapula.

21st, A.M. Breathing much easier; temperature, 99°; pulse, 100; respiration, 20; general condition much improved. P.M. Heart weak, somewhat irregular; temperature, 99⅘°; pulse, 100; respiration, 20.

22d, A.M. Heart somewhat stronger. Examination of urine showes traces of albumin, specific gravity 1020; no casts. Membranes present a dirty pultaceous appearance, and can be easily removed with a probe. P.M. Pulse regular, 78; temperature, 99⅘°; breathing easy.

23d, A.M. *Status idem.* P.M. Temperature, 99⅘°; respiration normal. Membranes have disappeared; urine negative. From this day on convalescence was uninterrupted. The temperature gradually fell, and was normal on the seventh day.

Case II.—M. D., six years of age, was seen by me October 3d. Extensive membrane on tonsil and soft palate. Temperature, 102°; respiration, 22; extensive tumefaction of glands; no involvement of the larynx.

October 4th. Membranes have extended over post-pharyngeal wall. Pulse, 110; temperature, 102½°; general condition depressed.

5th. *Status idem.* No antitoxine being available, the treatment followed the ordinary rules of practice.

To report this case *in extenso* would therefore be of no interest. The general condition of the patient remained bad until his death, which took place suddenly on the twelfth day of his illness. No antitoxine had been used in this case.

Case III.—Mary D., eleven months old, was taken ill on the 26th of October with diphtheria. No antitoxine available; death on the 28th.

Case IV.—John D., five years old, taken ill on October 27th. Membranes begin to form over tonsil and soft palate; pulse, 108; respiration normal; no involvement of the larynx.

October 28th, A.M. Injection of 1½ c.c. of antitoxine (Schering) near scapula; pulse, 108, regular; temperature, 102°; respiration normal. Extensive membranes over tonsils and soft palate; general condition depressed; urine negative. P.M. Temperature, 99⅘°; pulse, 108; membranes have not extended; general condition better.

29th, A.M. Temperature, 99⅘°; pulse, 108; membranes have a pultaceous fatty appearance and can be partly removed with probe; general condition good. Inoculated culture-tubes and sent them to

Dr. Ravenel, of the Hygienic Institute of the University of Pennsylvania, for examination. P.M. Temperature, 101°; pulse, 150; general condition less favorable; membranes presented a dirty yellow appearance.

30th, A.M. Pulse, 102; heart weak; temperature, 100⅘°; general condition fair. Dr. Ravenel reports vigorous growth of Klebs-Loeffler bacilli. P.M. Temperature, 99⅘°; pulse, 106, irregular; membranes coming away; general condition good.

31st, A.M. Temperature, 99°; pulse, 102, regular; throat almost clean, with exception of patch over right tonsils. P.M. Temperature, 99⅘°; pulse, 98, stronger.

November 1st, A.M. Temperature, 99⅘°; pulse, 98, normal. Urine negative. P.M. Temperature, normal; pulse, 96, strong; throat clean, with the exception of a small spot on right tonsil.

From this day on convalescence was interrupted only by a slight rise of temperature on the evenings of November 2d and 3d. Culture-tubes inoculated on November 6th and submitted to Dr. Ravenel for examination still show growths of Klebs-Loeffler bacilli.

CASE V.—Willie D., aged four years, was taken ill on the morning of October 28th; temperature, 101⅘°; pulse, 106; pultaceous spots on tonsils; cervical glands enlarged. Injection of 1 c.c. of antitoxine (Schering) near scapula. P.M. Pulse, 110; temperature, 101°. Pseudo-membrane has extended somewhat; larynx not involved; general condition fair.

October 29th. Temperature has fallen to 99°; pulse, 108; no extension of exudation in throat; general condition good; culture-tubes inoculated and submitted to Dr. Ravenel for examination. P.M. Temperature, normal; pulse, 146; heart weak; general condition not so good; no extension of membranes; urine contains traces of albumin and excessive phosphates.

30th, A.M. Temperature, 101⅘°; pulse, 116; heart weak and irregular; membranes have not extended, of a dirty-yellow appearance, can be removed with probe. Dr. Ravenel reports vigorous growth of Klebs-Loeffler bacilli. P.M. Temperature, 100°; pulse, 116, weak; general condition fair.

31st, A.M. Temperature, 99⅘°; pulse, 120, irregular; heart weak; membranes disappearing; urine contains traces of albumin. P.M. Temperature, normal; pulse, 102; heart still weak.

November 1st, A.M. Temperature, normal; heart weak; general condition fair. P.M. Temperature, normal; pulse, 117; heart weak.

2d, A.M. Temperature, 99°; pulse, 102; heart stronger; general condition good; throat clean; urine negative.

From this day on convalescence was interrupted by a slight rise of temperature, reaching 99°. Culture-tubes inoculated from throat on November 5th and examined by Dr. Ravenel were negative.

CASE VI.—The fifth child of this family, a little girl two years of age, remained apparently well. Her throat, however, showed a slight diffused redness. In this family of five children, who had freely commingled with each other even after the appearance of symptoms in the others, the probability amounted to almost a certainty that this little girl would not escape infection. The following effort at immunization was therefore made: ½ c.c. of Schering's antitoxine was injected on October 28th, her temperature at that time being 99°. On October 30th a second injection of 0.8 c.c. of Behring's antitoxine was made. Subsequently the congestion in the throat cleared up and the child remained well. Dr. Ravenel examined a culture from her throat on November 6th and found Klebs-Loeffler bacilli. It is important to add that the mother of these children, who has constantly been in attendance upon them, is at present writing suffering from the same disease.

I have ventured to report these few cases for the consideration of my colleagues, being well aware that their number is too small to permit of any definite conclusion as to the value of serum-therapy of diphtheria, all the cases, moreover, having been treated, in addition to the serum-therapy, according to the generally accepted rules of practice. Nevertheless, the cases here presented showed some features so striking that they appeared to be of interest. After each injection a rapid fall of temperature was noted, as you will see by the charts. This reduction, however, only lasted twenty-four hours, but when it would rise again, it was never to its original degree. In Case I, where two injections were made, the same phenomena were observed after each.

At the same time a marked amelioration in the difficulty of breathing was noted. The heart was much less favorably influenced, being often irregular and weak. Nevertheless, I feel that if a sufficient quantity of serum had been at my disposal, and repeated injections could have been made, the toxine still remaining in the circulation might have been more effectually neutralized and its depressing effects on the heart avoided. The behavior of the membranes was peculiar, inasmuch as they did not seem to thrive; they failed to spread, and in from twenty-four to forty-eight hours after the injection they assumed a fatty pultaceous appearance, and in each instance disappeared within a week. The cases as a whole ran a milder course. I do not think that the cases could be called mild ones, since the two children who had not been treated by antitoxine serum died. The continued presence of probably virulent Klebs-Loeffler bacilli in the throats of two of the other children would, I think, indicate that antitoxine serum does not kill the microorganisms themselves, but merely neutralizes their poisonous products, and that consequently isolation and poper disinfection of the throat is indicated as heretofore.

In conclusion, I desire to say that I feel very much indebted to Dr. Ravenel for his painstaking bacteriological examinations of my cases. I also desire to thank my friends, Drs. A. Klein and P. A. Trau, for their kind assistance in watching and keeping records of the cases.

My thanks are also due to Messrs. T. C. Laubach and L. B. Phillips, druggists of this city, who procured the serum for me, the latter gentleman being the first, I believe, who secured Behring's antitoxine in this city.

A GERMAN VIEW OF "AMERICANISM" IN MODERN MEDICINE.

A remarkable article has recently appeared in the *Deutsche Medicinische Zeitung*. The author's personality is modestly concealed under the pseudonym "B. L. in W." His doleful lucubrations have been widely copied by the medical press of the fatherland. The gist of B. L.'s terrible arraignment of modern medicine is that European, even including German, therapy is becoming rapdily "Americanized." How best to meet this depraved tendency in a downward direction is made the subject of his anxious inquiries.

The Teuton naturally stands aghast at the dismal vista opening before his dreamy eyes by the rapid strides of German medicine away from time-honored theorizing and scientific hair-splitting into the broad domain of common sense and the practical. That is what it means for German medicine to become Americanized.

If B. L.'s representations can be relied upon, there must be great alarm in the inner circles of German medical autocracy, where abstract science is still supposed to reign supreme, while German death-rates go on healthfully increasing.

We are told that "the American healing art has, without doubt, made extraordinary advances in the past few decades." It is indeed nothing short of disgraceful that the German public is beginning to ask the German doctors to cure German ailments on the American plan.

The involuntary confessions of B. L. disclose a peculiar state of affairs. For while America still sends its annual quota of callow youths to the empire of William II in quest of "higher medical education," the subjects of his majesty are clamoring for transatlantic notions in the conduct of medical practice. Now the *Record* has always believed in reciprocity. For this reason we will welcome to our shores all those German graduates who, after having been drilled in approved Teutonic methods of pure science, find themselves a trifle deficient in those minor qualifications of professional power which help to cure the patient. At the same time we are willing to send some of our own medical citizens across the water, in order to find out the best-sounding Greek names for diseases which they have long known how to handle, though not, perhaps, to euphoniously designate. A fair exchange on such lines ought to be helpful all around.—*N. Y. Med. Rec.*

EDITORIAL.

THE PARASITES OF VARIOLA AND VACCINIA.

At the Eleventh International Medical Congress there was an interesting discussion on the etiology of variola.

Guarnieri gave the results of his investigations of the forming pustules in variola, in which he found a microörganism to which he gave the name *Cytoryctes vaccinia*, and he devoted his paper largely to the morphology of the organism which he believes to be the cause of variola. This organism was observed in a hanging-drop preparation to have amœboid movement. It was observed to move in a fresh preparation from the contents of a beginning pustule when examined on a warm stage. It was also observed to divide. When properly stained with methyline blue mixed with blood-serum the *cytoryctes* show a rounded mass or body within the organism which stains very slightly, surrounded by a clear space.

At the same meeting Monti gave the results of his investigations into the etiology of variola. He has studied bacteriologically the contents of a large number of vesicles and pustules from about ten cases of small-pox, and with great constancy found in the pus *Staphylococcus pyogenes aureus* and a microphyte of the normal epithelium. He also examined in a similar manner cases of *purpura variola* where the patients died in the early stages of the disease. In these cases the cultures remained clear or developed very few colonies of known epidermal bacteria. Anaërobic cultures gave negative results.

A microscopical examination, however, of the hemorrhagic cases discovered in the epithelial cells of the Malpighian layer nests of hemorrhagic points containing characteristic bodies which stained readily, after the method of Biondi, with hæmatoxylin and with a special mixture of hæmatoxylin and safranin. These bodies were sometimes very small; sometimes from two to three micromillimeters in diameter. They varied somewhat in form, occasionally resembling the figure 8. Ordinarily each epithelial cell contains a single organism in a mass of protoplasm. The nuclei of the epithelial cells were more or less obscured by the organisms. Control examinations of other diseases gave negative results.

The constancy with which Monti found these bodies in five cases of hemorrhagic vesicles and in the prepustular stage, led to certain investigations with this substance on the cornea of rabbits. He noted that after inoculating the eye with the infected substance he found the same bodies in the surrounding cells, but with similar inoculations with other substances the wound healed perfectly in a few days.

These results led him to the conclusion that the organism described was the cause of variola or small-pox. Monti did not think that these organisms belonged to the same class of protozoa entertained by Guarnieri, but to a much simpler class of organisms, the *Lobosi*.

Since the introduction of bacteriological methods a host of observations and experiments have been made to determine the etiology of vaccinia. A few more recent observations are of interest, yet the results are still quite contradictory.

Klein (Supplement to the Local Government Report containing the report of the Medical Officer for 1892–93, London, 1894) gives the results of several investigations of calf lymph. The results are similar to many other bacteriological investigations, inasmuch as a great variety of bacilli, *streptococci*, *staphylococci*, etc., were found.

He differs, however, in finding a bacillus which appears to be characteristic of the lymph. So numerous were these bacilli that in cover-glass preparations made from the lymph they would easily be mistaken for preparations of pure cultures. They are frequently (always in seventy-two-hour lymph) in clumps. The majority of the groups included from three to eight bacilli. They contain globules which Klein believes to correspond to spores.

He was, however, unable to cultivate this bacillus on artificial media or in the subcutaneous tissue of a calf.

ABSTRACTS.

MINISTERIAL INDORSEMENTS OF HUMBUGS.

We are sorry to see the names of Christian ministers and persons occupying important positions in the Church circulating through the country indorsing barefaced frauds which are poorly executed, and no better than Indian charms. Whenever a minister of the Gospel allows his name to be attached to anything whose advertisements make statements impossible of fulfillment, or contrary to established principles of science, and especially to be mixed up with all sorts of testimonials written obviously by the most ignorant and uncultivated persons, he loses the respect, and justly, of that class of the community which in the long run fixes the estimate in which he is held.

This, together with similar exhibitions of weakness, often accounts for the failure of young men who otherwise give bright promise of success, and the early retirement of those who in spite of them had attained a good standing.

In the interest solely of our readers we advise them to pay no attention to a ministerial testimonial to remedies whose composition is a secret, or which promise positively to cure otherwise incurable or generally fatal diseases. And all the more so if the testimonial contains references to the Almighty and providential direction to buy the medicine. You may be sure then that whatever other effect the remedy has had, it has either weakened or has not improved the condition of the nerve cells upon which sound judgment depends.

When ministers go further and surrender their photographs to patent medicine venders to be used in advertisements and on bottles, they render themselves liable to one of two suspicions: Either that they have an inordinate desire to appear before the public, in which case such extravagant vanity must weaken their influence; or that they have received

a compensation for the privilege. For, that quacks of all sorts are ready to pay largely for certificates from physicians, for editorial notices, and for the privilege of publishing letters from and photographs of clergymen, cannot be doubted.

Not only do they thus render themselves liable to suspicion, but they grieve every truly refined member of their congregations, and every member, in fact, of their denomination who sees their pictures and letters displayed for such purposes. Could many of the ministers know what is said of them, self-interest would lead them to refuse in every case. It should be taken as an insult by every minister of the Gospel of Christ to be asked to furnish his photograph, or to consent to its use, as a part of a patent medicine or any other advertisement.

In one instance the name of such a person was proposed for the pastor of one of the best churches in Methodism. A brother of high character and respectability, noted for his kindness when speaking of ministers, rose and said: "I hope that this brother will not become our pastor." "Why?" said half a dozen voices. He did not reply, but spread before them a newspaper containing the photograph of the minister, in connection with three or four letters, one from himself interlarded with ascriptions of praise to the Deity for having led him to buy the —— pills. His name was not mentioned again.—*Christian Advocate.*

THE DIAGNOSIS OF TUBERCULAR JOINT DISEASE.

A. G. Miller, F.R.C.S.E., Surgeon to the Edinburgh Royal Infirmary, writes (*Edinburgh Med. Jour.*, November, 1894): In my experience as a hospital surgeon I have not infrequently seen mistakes made in the diagnosis of tubercular joint disease. From the statistics of the hospital reports, I gather that the proportion of tubercular to all other joint affections is from three-fourths to four-fifths. In this calculation I no not include spinal or sacro-iliac cases —only the joints of the extremities.

I have drawn almost entirely from my own experience. Consequently my views may not coincide with those of other surgeons. I give them, however, to the profession for what they are worth, hoping that they may be of use to some.

The affections that in my experience are liable to be confounded with chronic tubercular joint disease are the hæmophilic joint; the hysterical joint; sarcoma; chronic traumatic synovitis; syphilitic synovitis; chronic rheumatoid arthritis; tubercular epiphysitis; tubercular bursitis; and tubercular teno synovitis. Before dealing with the differential diagnosis of chronic joint tuberculosis from these various affections, I would first point out what I believe to be the leading and most reliable characteristics of chronic tuberculosis of the joints of the extremities. These are mainly six:

1. Mode of onset—history of slight injury or none.
2. Appearance of joint—pale, ovoid, smooth, etc.
3. Temperature of joint slightly raised.
4. Absence of pain, except on movement.
5. Limitation of movement by muscular spasm.
6. Atrophy of muscles, especially of the extensors.

1. The mode of onset. The patients who mostly come to us with tubercular joints (children and adolescents) are very liable to have injuries, and they are so accustomed to these that they think nothing of them, but immediately forget them. Older patients are very apt to remember, or at any rate to classify, their diseases by the treatment to which they have been subjected on their account. An injury, consequently, that has received no treatment is generally forgotten. There may be no history, therefore, of an injury, and the onset is said to have been insidious.

On the other hand, we often get a history of a slight injury which caused a slight amount of swelling, hardly sufficient to oblige the patient to remain in bed—or perhaps only for a short time. The patient goes about, limps a little, or is stiff and constrained in some movements (if the upper extremity is affected), and perhaps cries if roughly handled. The joint never gets well. The swelling comes and goes, but never quite disappears. Movement becomes more restricted and painful.

Up to this point inflammation is not feared by the parents, because the joint is not apparently inflamed. Sometimes, however, a bonesetter is consulted, on the supposition that the "joint is out." He wrenches the limb and makes things much worse, and then orthodox advice is sought. Every hospital surgeon knows that this is a very common history which I have been trying to sketch.

I believe, therefore, that all these cases originate in a slight injury (I never saw one which originated in a severe one), which is not treated and forgotten, or is treated in such a way as not to bring about a perfect recovery; that is to say, the joint is never properly rested.

2. Appearance of joint. The pale and rounded or ovoid appearance of the joint is, of course, well known, having originated the ancient title of "tumor albus." The skin looks wonderfully natural. There is, however, a smoothness, due to the obliteration of the normal folds and furrows, which is peculiar. There may be some unusually distinct superficial veins and a number of long silky hairs—if the patient be old enough.

The normal prominences of bone, which give the distinctive external features to each joint, are smoothed down or obliterated by the swelling which gives the characteristic rounded or ovoid appearance to the tubercular joint. This condition is sometimes made out properly only on careful comparison of the affected joint with the normal one. The smooth rounded appearance is explained by the slow increase and œdematous character of the swelling. That is to say, the swelling is an œdema, and as it occurs very slowly, it has time to find accommodation in the hollows and convenient slack places in and around the joint, where there are no restraining attachments of ligaments and tendons.

3. Temperature of joint. This is usually slightly, but distinctly, raised as compared with the corresponding healthy joint. This rise of temperature is always present and denotes the existence of an inflammatory process in the joint. Now, it must be remembered that this inflammatory process is not a slight one, though external appearances and subjective symptoms may tempt us to suppose so. I have learned and I teach that the amount of disease present is always in excess of the apparent symptoms. When one cuts into a tubercular joint, one is often surprised to find the amount of disease and destruction that is revealed.

The general temperature of the patient may be raised also, but sometimes it is normal or even subnormal. If raised, it follows a somewhat irregular course, and the highest point is not registered in the evening, as in other inflammatory affections, but often in the afternoon.

4 and 5. The fourth and fifth symptoms I will take together, because they are mutually dependent and explanatory. These two conditions are absence of pain except on movement, and limitation of movement. I might perhaps divide this very characteristic condition of strumous joints into three: 1, apparent absence of pain; 2, pain on attempts at passive movement; and 3, limitation of movement on the part of the patient. This double or triple (as you take it) condition of a joint I consider very characteristic of strumous disease.

We all know how patients can walk into hospital (limping perhaps more or less) with a hip, or knee, or ankle joint which is distinctly diseased, and perhaps has been so for some months. Again, a child may come to us who holds an arm in a rigid manner, who nurses it carefully, and who is very suspicious of its being handled; and yet the parents will say that it does not complain of it except when it is touched.

We know how surprised students often are when they are told that such joints are tubercular and require to be excised; and how still more surprised and terrified the parents are when told that an operation is necessary.

The absence of pain is what deceives. And it is ignorance that a joint may be far gone with strumous disease and yet apparently painless (except on movement) that leads to the destruction of so many joints; for the early stage of the disease is overlooked or not diagnosed, and the only period during which perfect recovery can be obtained, by proper treatment, is lost. Pain on movement is not a symptom peculiar to strumous joints, but absence of pain except on movement, associated with more or less fixation of the joint, is, I think, peculiarly characteristic of tubercular disease.

The absence of pain is due to fixation of the joint and to the slight degree of in-

flammation present. The latter is subacute and chronic. At the same time, though slight in degree it is extensive, as I have already said, because it usually involves, sooner or later, all the tissues constituting the joint—bone, cartilage, periosteum, synovial membrane, ligaments. The condition is arthritis—that is to say, an affection of the joint as a whole, and not a synovitis merely, as it is sometimes designated. This latter peculiarity of strumous disease explains the characteristic pain on movement, for with movement one (or more) of these structures is hurt and pain results. They cannot all escape. Indeed, they are all more or less hurt by movement. The absence of pain, therefore, is only apparent, being due to the involuntary fixation of the joint by the patient, to prevent the pain that would be caused by movement. The apparent absence of pain and the fixation of the joint have the same explanation, and that is why I have bracketed them together.

That the rigidity of the joint is due to muscular spasm is easily demonstrated in the early stages of the disease (before destruction of tissue and adhesions have taken place) by placing the patient under chloroform, when free movement of the joint is at once obtained.

The explanation of this muscular contraction or spasm is well known—it is reflex. By an impulse sent from the diseased joint to the spinal cord, and a reflected impulse sent to the muscles acting on the affected joint, the latter is fixed or splinted and painful motion prevented. In this way nature tries to bring about recovery, and has suggested to surgeons the method of treatment that has hitherto been most successful, viz., immobilization.

The affected joints (hip, knee, elbow) are generally not only fixed, but bent. This is explained by the well-known fact that the flexors are more powerful than the extensors; and the joint is usually more comfortable when bent than when straight, probably from the same cause. This rigidity or fixation is not confined to tubercular joints. We see an example of it in hallux rigidus. There the great toe is splinted on account of the existence of an arthritis. We see the same rigidity in the spine in early caries.

6. The last symptom which I would refer to as specially characteristic of tubercular joint disease is atrophy. This atrophy has many points worthy of consideration:

1. It affects the whole limb more or less.

2. It is greater and more rapid than can be explained by mere want of use.

3. It is more marked than in any other joint affection.

4. It specially affects certain muscles and groups of muscles; each joint having its peculiarities, which are very constant.

1. In strumous joint disease the whole limb atrophies. This is well known and I need not dwell on it. Witness the shrunken and wasted limbs in hip, knee, shoulder or elbow disease. There are two points, however, to which I would like to draw attention. The atrophy is not limited to the muscles, but affects the limb as a whole, and in the second place, this atrophy of the limb is apt to persist even after recovery of the diseased joint. Of this there are many examples, which must readily occur to the minds of all surgeons. I repeat, the atrophy is of the limb as a whole, muscle and bone alike, and it tends to persist. What is the explanation? I believe that the cause is a reflex contraction of the arteries of the limb which interferes with nutrition. I have been led to that opinion by observing, when I have had occasion to amputate for tubercular joint disease, that though there may be many active vessels in the neighborhood of the disease, the main arteries are always very small. I have often observed the latter about half the size one would expect them to be under ordinary circumstances —in a primary amputation, for instance.

2. The atrophy is greater and more rapid than would be caused by mere want of use. This, I think, is now generally admitted and recognized. There are several facts which go to prove this. We have seen, for instance, that when cases present themselves for treatment the limb is still being used to a certain extent; yet there is in such cases always well-marked atrophy.

3. The atrophy in strumous disease is more marked and rapid than in any other joint affections. This statement I cannot prove by statistics; I speak merely from experience. I thoroughly believe this, and more than once a rapid and extreme atrophy has made me suspect tubercle, the diagnosis being subsequently confirmed.

Muscular and general atrophy is usual in joint affections; but, I repeat, it is most marked in strumous disease.

4. The atrophy specially affects certain muscles and groups of muscles. These are, stated generally, as follows: Hip, glutei; knee, quadriceps extensor; ankle, extensors; shoulder, scapular muscles; elbow, triceps and biceps; wrist, muscles arising from internal condyle of humerus.

I take these merely as examples. The flattening of the hip and loss of the natal fold on the thigh are well-known signs of hip disease. The wasting of the quadriceps extensor in disease of the knee joint is also familiar. When one examines the thigh in such a case, it is wonderful how little seems to lie between the skin and the femur on the front of the thigh. Then in disease of the shoulder the prominence of the spine of the scapula from the wasting of the supra and infra spinati muscles is very evident, as also the prominence of the acromion from wasting of the deltoid.

Pathological Note. — The usually accepted explanation of atrophy is that it is due to a reflex action through the trophic centers in the anterior horns of the spinal cord. But why does the atrophy affect certain muscles earlier and more than others? Hilton* has pointed out that the same nerves which supply any joint supply also the muscles acting on that joint. In this way he explains the unconscious fixation of a diseased joint which always occurs and to which I have already referred. In the same manner he explains the flexion that usually takes place (knee and elbow) by the greater power of the flexors over the extensors. But he does not explain the atrophy. Ferrier† does this by telling us that extensor muscles are always earlier and more quickly atrophied than the flexors, because they are the weaker. "The vitality of the extensor centers and nerves is the first to become exhausted by any condition tending to lower the vitality of the nerve centers and nerves in general."

Charcot‡ has shown that muscular atrophy from disease of a joint is not the same as that from want of use—the latter being a fatty degeneration, which the former is not. He was of opinion that nerve irritation alone is capable of determining rapid and early atrophy of muscles, and that the diseased-joint irritation does so markedly, because its irritation is continuous. He points out also that atrophy started by joint disease is apt to persist and to cause general atrophy of the limb (to which I have already referred). In the *British Medical Journal** there are references to investigations made by German and French observers, who found a simple degeneration in the atrophied muscles connected with joint disease. The muscles "were obviously atrophied and of a paler color than those on the other side, and they had lost their firmness and elasticity." The microscope showed "no trace of degeneration," but the "fibers were considerably smaller than they should be." This, it appears to me, points to what I have already suggested in my paper on Bier's method of treating tubercular joints by congestion, viz., that the reflex action, acting through the trophic centers in the anterior horns of the cord, causes a contraction of the arteries. It seems natural to suppose that diminution in the size and power of a muscle should be due to a diminished blood supply; and if the object, so to speak, of a reflex action is to cause atrophy of a muscle, surely the quickest and surest way would be to shut off the blood supply. Then one must remember that though the atrophy begins in certain muscles, it ultimately extends to the whole limb and tends to persist.†

Muscular atrophy cannot be due to muscular spasm in the cases we are considering, because the muscles affected with spasm are not those most atrophied—*e.g.*, in the case of the knee the hamstrings are most contracted and the quadriceps is most atrophied. Again, this theory will not explain the atrophy of a whole limb—muscles, bone and all.

Another explanation has been offered of the muscular atrophy in tubercular joint disease: for instance, of the deltoid in shoulder and the quadriceps extensor in knee affections, viz., that the tubercle bacilli enter the muscular substance from the subjacent joint and cause a low form of inflammatory process which produces

*"Rest and Pain," second edition, p. 150

‡"Diseases of Nervous System."

*Epitome, January 24 and July 11, 1891.

†In Holmes' "System of Surgery," vol. ii, p. 209, several instances are given of muscular atrophy resulting from contraction of blood-vessels from reflex causes and neuralgia; and an instance is given of atrophy of the muscles of the thumb and hand due to an injury to the ulnar artery.

the atrophy. No proof of this has, however, been adduced; indeed, as we have already seen, the atrophy has been proved to be a simple one, unconnected with any degenerative or other change in the substance of the muscles themselves.

At the same time, one must admit that it is very likely that the muscular substance is tubercular in some way, for it has been demonstrated that muscle from tubercular animals, although it may seem perfectly sound and good, is capable of infecting guinea-pigs with tuberculosis.

In what way is the apparently healthy muscle infective? Does it contain spores? Are bacilli derived from the blood and lymph vessels? How do the lower animals get their tuberculosis? Why has muscle tubercle not been observed in man? These are questions that suggest themselves, but cannot, of course, be discussed in this paper.

The Strumous Joint.	*The Hæmophilic Joint.*
1. Slight injury or none.	1. Injury, often slight.
2. Joint pale, ovoid, slightly warm, boggy (seldom fluctuating; patella fixed in knee case), and synovial membrane thickened (œdematous).	2. Joint pale or slightly discolored, rounded in outline (shape that of simple synovitis), warm, boggy or fluctuating (in case of knee patella, movable).
3. Limb fixed, movement painful and resisted by muscles.	3. No fixation or pain on movement if performed gently.
4. Marked muscular atrophy, especially of extensors.	4. Muscular atrophy not a sympt m.
5. Presence of tubercular affections elsewhere.	5. Marks of ecchymosis.
6. History of tubercle in family.	6. History of hæmophilia among males of family, transmitted through females. History of former bleedings from cuts; epistaxis, etc.
7. Patient delicate-looking.	7. Patient delicate-looking.
8. Rest will not bring about a cure in a week or two.	8. Rest will cure in a week or two.

I now take up the subject of differential diagnosis, and this will have been made more easy by the fullness with which I have gone into the diagnostic points of tubercular disease.

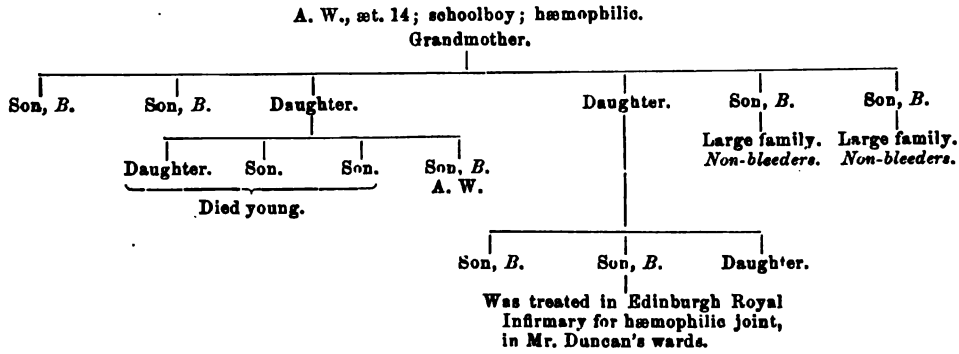
I. The first affection I take is the hæmophilic joint. The hæmophilic joint is very like the tubercular. There is usually a history of a slight injury. The joint is pale, rounded in outline and not painful. Flexion, however, may cause pain. There may be some muscular atrophy. The child is delicate-looking and may have a suspicious family history, some relatives having died of tubercular disease. The diagnostic points on which I would rely are: 1. Movement of the joint is fairly good and is not resisted by muscular reflex, because it is not painful if done gently. 2. Muscular atrophy, if present, is not marked and does not affect special muscles as in tubercle. 3. Marks of ecchymosis may be present, both recent and ancient. It is quite legitimate in a doubtful case to pinch the child and look next day for an exaggerated ecchymosis, which is sure to occur in a hæmophilic case. 4. The history of previous epistaxis, or bleeding from cuts, is a valuable help. 5. If the joint, or some other, has been affected previously, it will have recovered with perfect restoration of function—a state of matters that does not occur, in my experience, in tubercular disease. 6. Then there is the family history. Bleeders appearing among the males, but transmitted through the females of the family. 7. Lastly, time will show. In a few days there may be discoloration over the joint from the soaking through of the blood in the joint, and in a few weeks the joint will get perfectly well if it is rested. This, of course, will not occur in a tubercular joint (more the pity).

In this connection I would like to record the case of a boy who has been frequently under my care for hæmophilia.

A. W. came under my care first when about four years of age. He had an enlarged knee joint, which was diagnosed as white swelling, partly from its appearance and partly from the history of his father having died of phthisis. The joint was treated by rest and improved somewhat. As there was great restlessness on the part of the patient and some suspicion of starting of the limb, the actual cautery was applied. This at once demonstrated the true nature of the case, because when the sloughs separated bleeding commenced and nearly proved fatal. The joint recovered perfectly. Since then the boy (who is now fourteen years of age) has frequently been under my care for epistaxis, cut fingers and effusion into a knee or an elbow joint. When last seen he was perfectly well, not a trace being left

of any of his joint affections. His family chart, which is very typical, is appended.

II. The hysterical joint is sometimes very difficult to diagnose from strumous disease. I have treated several cases in which the hip and knee were affected. Two cases of hysterical hip occurred in ladies, two in boys. The two former got well under massage, counter-irritation and change of air. The two latter were cured



at once by circumcision. Two knee cases were females, one of whom has been under treatment for several years.

In regard to the question of diagnosis, the points I would depend upon are: 1. Numerous and changing painful spots. 2. Want of definiteness and accuracy in symptoms. There is a difficulty in making out what the condition really is, and there is not a true ring in the symptoms. 3. The patient has the peculiar "shifty" look of hysteria, which I cannot describe, but which is generally easily recognized once attention is directed to it. The ovaries may be tender, etc. 4. All symptoms disappear under an anesthetic and reappear on the patient recovering consciousness.

The Tubercular Joint.	*The Hysterical Joint.*
1. Joint pale, ovoid, hot, boggy; large veins, hairs, etc.	1. Joint enlarged; nothing definite to be made out.
2. Joint fixed; movement painful.	2. Joint fixed; movement resisted.
3. Pain not a special symptom.	3. Hyperæsthesia; pain at varying points.
4. Marked muscular atrophy, especially of extensors.	4. Limb may be smaller, but there will be subcutaneous fat.
5. History of tubercle, and perhaps presence of tubercle elsewhere.	5. History of nervous complaints. Evidence of hysteria; ovaries sensitive, etc.
6. Disease progressive, or else improving under treatment.	6. Disease stationary and no improvement from local remedies.
7. Under chloroform distinct evidence of disease.	7. Under chloroform all symptoms disappear.

III. Sarcoma of the lower end of the femur I have seen mistaken for tubercular knee joint, and I have seen several cases of advanced tubercular disease of the knee that resembled sarcoma in external appearance. I could imagine the same sort of thing in connection with the shoulder and other joints. The resemblance is in appearance—that is to say, it is external and superficial. Both conditions present a swelling in the neighborhood of the joint, smooth, rounded or ovoid in outline, with engorged superficial veins coursing over it; warm to the touch; soft, elastic, perhaps fluctuating; often especially soft at one point as if pointing. The patient is probably young and delicate looking, gives a history of an injury followed by a swelling, which enlarged slowly at first and then more rapidly. There is muscular atrophy of the limb. The resemblance to white swelling is considerable, but on closer investigation we find in the case of a sarcoma that the swelling began on one side (where the injury probably had been) and was small at first and localized. At this time the patient is perfectly healthy. But he begins to show evidences of delicacy and wasting after the swelling has existed for a month or so and after it has begun to grow more rapidly and to cause pain. We find also that the swelling takes only a month or two instead of several months to grow. Then on examining

the part locally we find that the joint is really not involved. Movement is possible (within certain limits) if carefully performed, there being no true splinting of the joint. The swelling is somewhat to one side, and the patella, though lifted up, is usually on one side. There may be pulsation. Atrophy, sometimes considerable, is more general than in tuberculosis.

It will be seen that I refer to advanced cases—*i.e.*, of several months' duration.

White Swelling.	*Sarcoma.*
1. History of slight injury.	1. History of injury.
2. Joint pale, ovoid, warm, boggy; enlarged veins, hairs (if suppuration, fluctuation, pointing).	2. Swelling near joint; smooth, rounded, warm, elastic, large veins; may fluctuate at parts.
3. Limb fixed; movement painful.	3. Healthy joint can be made out.
4. Marked muscular atrophy, especially of extensors.	4. Muscular atrophy general.
5. Tubercular history and tubercle elsewhere.	5. No tubercular history; patient healthy till tumor began to grow.
6. Comparatively slow growth.	6. Comparatively rapid growth.
7. Slight rise of temperature, which is irregular.	7. If rise of temperature, it is steady.
	8. Growth commences at one side; may pulsate.

It is only in such that I have seen difficulty in diagnosis. In early cases there ought to be no difficulty.

IV. Chronic traumatic synovitis may be diagnosed from white swelling by—

1. The history. Injury usually pretty severe. Sharp, acute synovitis not completely cured. Family history good.

2. Movement fairly free and not painful, unless there are adhesions.

3. If adhesions, then flexion is painful only when adhesions are put on stretch. In other words, movement is free and painless up to a certain point.

4. No marked muscular wasting. If present, is general and not special. To put the thing in a nutshell, this is a synovitis. The tubercular affection is an arthritis.

5. Swelling shape of synovial membrane, with fluctuation (floating patella in case of knee). Thickened synovial membrane may be felt at margin sometimes.

In this connection I would like to say a few words on two points: 1, adhesions; 2, thickened synovial membrane.

1. Adhesions. The diagnosis of these adhesions is usually easy, and they, if present, aid the general diagnosis very much. The diagnostic point is freedom of movement and painless movement *up to a certain point.* Then come both pain and fixation of the limb by the patient. This is seen best in the knee and is very characteristic. The knee may be used fairly well in walking, but if an attempt be made to fully flex the joint, acute pain is produced when a certain angle is reached and the patient at once resists. Sometimes the patient, anticipating the painful stage, resists the flexion before the adhesion-point is reached. This is very different, however, from the general spasm and fixation of the limb, or splinting by muscular contraction, that occurs in tubercular arthritis.

Strumous Arthritis.	*Chronic Traumatic Synovitis.*
1. Slight injury or none.	1. Pretty severe injury.
2. Joint pale, ovoid in outline, slightly warm, boggy; synovial membrane œdematous.	2. Joint pale, swelling shape of synovial membrane, fluctuation, synovial membrane thickened.
3. Limb fixed by muscular spasm.	3. Joint movable, unless adhesions, when movement arrested abruptly at certain point.
4. Marked muscular atrophy, especially of extensors.	4. Muscular atrophy slight and general, not special.
5. Tubercular history and tubercle elsewhere.	5. No tubercular history or manifestation.
6. Slight rise of temperature, of irregular type.	6. Temperature normal.

2. Thickened synovial membrane. This is most easily made out by pressing on the margin of the synovial membrane. In the knee, for instance, at the upper edge of the pouch above the patella. This thickening differs from the œdema of tubercular disease by being firmer, denser and more defined. This can be easily understood when we consider that the one is a genuine hypertrophy of the synovial membrane, the other an inflammatory œdema.

V. I shall next consider syphilitic synovitis, which I have met with almost solely in the knee joint. This should not be difficult to diagnose from tubercular disease, though it is sometimes difficult to differentiate from simple chronic synovitis and chronic rheumatoid arthritis. The main point of distinction is the history of the case. Previous history of syphilis, no

traumatism; not infrequently bilateral; not giving way to ordinary treatment, but improving under mercury locally and potassium iodide internally.

VI. Chronic rheumatoid arthritis may be mistaken for tuberculosis. I think that they are not infrequently confounded, and I have seen cases in which only animal inoculation could possibly have decided the matter. In advanced cases of both diseases you have involvement and ultimate destruction of all the tissues forming the joint. The synovial membrane is thickened, the cartilage is destroyed, the bone is inflamed, and the ligaments are softened and stretched, permitting lateral movement accompanied with grating. You may have suppuration in either case

In early cases of chronic rheumatoid arthritis I would rely for diagnosis on—(1) the condition of the bone; (2) the presence of fluid; (3) the affection of other joints; (4) condition (pain especially) affected by changes in the weather.

In advanced cases, in which somewhat acute symptoms have supervened and in which there is softening of the bones (carpus), still more if suppuration have occurred, diagnosis from tubercle is more difficult. But this is of less importance, because the treatment is the same, viz., excision of the joint or amputation. These latter cases may be, I am quite prepared to admit, genuine tuberculosis in-

Strumous Arthritis.	*Syphilitic Synovitis.*
1. Slight injury.	1. Came on slowly.
2. Joint ovoid and boggy.	2. Joint shape of synovial membrane; fluctuating.
3. Rigid and painful on movement.	3. Painless, movable, but weak.
4. Atrophy marked and special.	4. Atrophy slight and general.
5. May be multiple, but not symmetrical.	5. Sometimes symmetrical.
6. History of tubercle.	6. History of syphilis.
7. Tubercle elsewhere.	7. Traces of syphilis elsewhere.
8. Not materially benefited by mercury and K. I.	8. Benefited by mercury and K. I.
9. Increase of temperature.	9. No increase of temperature.

grafted on chronic rheumatoid arthritis; but, as I have already said, animal inoculation could best decide that.

VII. The last condition that I shall contrast with tubercular arthritis is tuberculosis occurring near but not in a joint. Under this head are tubercular epiphysitis and tubercular bursitis. The former may involve the joint early and thus become an arthritis or may give rise to an epiphyseal abscess. The diagnosis ought to be easy, and in my experience there is usually no difficulty.

The point most to be relied on is the fixed pain in the epiphysis, increased by pressure, but not by gentle movement, and generally worse at night. In short, the localizing of the disease in the epiphysis, and not in the joint, settles the diagnosis.

In regard to tubercular bursitis he diagnosis is sometimes not so easy. The

Tubercular Arthritis.	*Chronic Rheumatoid Arthritis.*
1. Patient usually young.	1. Patient usually advanced in life.
2. Tubercular history.	2. History of rheumatism or gout, or both.
3. Tubercle elsewhere.	3. Chronic rheumatoid arthritis elsewhere.
4. Joint ovoid and boggy.	4. Ends of bones enlarged; synovial membrane thickened and containing fluid.
5. Joint fixed; pain on movement.	5. Pain on movement, perhaps grating; joint not fixed.
6. Muscular atrophy, especially of extensors.	6. Muscular atrophy general.
7. Not affected by weather.	7. Affected by weather.
8. Slight rise of temperature, which is irregular.	8. No rise of temperature generally; rather subnormal.

Tubercular Arthritis.	*Chronic Tubercular Epiphysitis.*
1. Joint enlarged, ovoid, boggy, etc.	1. Joint free; swelling above or below joint.
2. Pain not a prominent symptom, only on movement.	2. Pain on pressure on epiphysis; worse at night.
3. Joint fixed, etc.	3. Joint not fixed usually.
4. Atrophy of muscles, etc.	4. Atrophy not so marked and not "special."
5. No special œdema of limb.	5. Limb œdematous below diseased part; slight collection of fluid in joint (symptomatic).
6. Slight rise of temperature, which is irregular.	6. Rise of temperature more marked.

bursæ that I have seen most affected are —(1) that over the trochanter major; (2) under the tendon of the psoas and iliacus; (3) over the patella; (4) under the ligamentum patellæ; (5) under the deltoid. The first two may be confounded with hip-joint disease. The treatment, however, is practically the same, so an error does not much matter.

I have found these bursal affections usually connected with disease of the underlying bone. Whether the disease commences in the bone or the bursa, I do not know; but I would be inclined to suspect the bone. I always treat these cases as if they were joint disease. The general diagnosis depends, as in the former instance, in localizing the disease. If the joint be healthy the disease must be elsewhere. Pain, swelling, etc., will then localize the diseased condition.

There is another affection to which I might refer here, viz., tubercular tenosynovitis; but the differential diagnosis of this from tubercular arthritis should not be difficult in any ordinary case.

In conclusion, I wish to say that I do not submit the above descriptions and remarks as exhaustive of the subject. They are intended, being the outcome of my experience as a hospital surgeon during the last twelve years, to be an aid to others who may not have had as much experience in tubercular joint disease.

SOCIETY REPORTS.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Section on General Surgery.

Meeting of November 9, 1894.

William J. Taylor, M.D., presented a paper on

WOOD-PULP SPLINTS AND SPLINT MAKING MATERIAL, AS SUGGESTED BY DR. E. A. TRACY, OF BOSTON.

I have here a number of splints made from a new material, the invention of Dr. Edward A. Tracy, of Boston, and which he was kind enough to send me, along with some of the sheets of the material itself. You have probably all seen the article by Dr. Tracy in the *Medical News* of March 17, 1894, entitled "A Brief Splint-Technology for Surgeons." When I read the article I was so much impressed with the probable value of the material for splint-making that I wrote to him, and it is in answer to this letter that he sends me these samples.

All of these splints were made by him and have been in actual use at the Boston City Hospital. He writes me that "the results to be gotten will repay the trouble of acquiring the proper technique—and this trouble is but slight."

The material is best described by Dr. Tracy's article, just referred to, and of which the following is an abstract: "The basis of the material is wood-pulp, made preferably from the crushed fiber of the poplar tree, and rolled in such fashion that the broken fibers intertwine in every direction and loosely, so that an increase of plasticity is thus given the product. These sheets are further strengthened by having a fabric introduced between the layers of the pulp, or by interweaving with the short, crushed wood-fiber, a long jute or other tough fiber.

"The sheets are rolled of different thicknesses, and are numbered one, two and three, according to their thickness in millimeters.

"The chief characteristics of this material are stiffness or rigidity when dry and plasticity when moist. Its rigidity can be increased *ad libitum* by the use of a silicate solution as a moistener. Its plasticity has a limit, but this is rarely reached except when molding the material over certain complex curved surfaces. Besides the foregoing characteristics, the material possesses that desideratum of a splint material—extreme light-

ness. Its cheapness also deserves passing mention.

"Water or a stiffening solution can be used to moisten the material. If water is used the splint must be protected from the perspiration, lest it soften, by a covering of oiled silk or paper, or best by shellac. A stiffening solution with several qualities to recommend it is that of silicate of potassium; silicate of soda is almost as serviceable. Any desired degree of rigidity can be imparted to a splint by using this solution—the amount of rigidity depending upon the strength of the solution. Dextrine in the proportion of 8 ounces to the pint of water adds some tenacity besides stiffness. A splint made with its aid can be moistened with water and remolded—quite an advantage in many cases.

"In using this material the aim should be to get barely sufficient moisture to render the material semi-plastic. If more moisture is absorbed it becomes difficult to maintain the molded splint in the desired shape while drying, and it also unnecessarily lengthens the time required to dry it. The best manner of moistening the splint blank is to apply the fluid used on each side of it alternately by means of a flat paste-brush. A little practice will enable one to judge the precise amount of moistening best suited to the purpose. The time required for drying the molded splints varies from ten to forty minutes, according to the thickness of the material used; any source of heat can be employed, a kitchen fire being serviceable and nearly always at hand.

"While drying the splint after it is molded to fit the part, it is well to wind a bit of yarn or string around it to aid in retaining its shape until it is sufficiently hard to keep its form"

He then describes in detail the application of splints made from this material to different portions of the body, including the head, the trunk, and the upper and lower limbs.

As I have only just recently received the material my personal knowledge of the technique is limited, but I can readily see the ease with which the sheets can be molded to fit inequalities in the limbs. The extreme lightness of the splint will be of the greatest service in many cases, and will be much more comfortable to the patient than the heavier and more cumbersome splints in common use. Then, too, by coating the splint with a silicate solution, it becomes impervious to moisture and can be washed daily with an antiseptic solution.

Dr. J. B. Roberts read a paper on

THYROIDECTOMY IN THE TREATMENT OF GOITRE.

(See page 754.)

DISCUSSION.

DR. G. A. MUEHLECK: I have a case under observation at present with a well-marked hypertrophy goitre which I am treating after the method of Garé, which is practiced at Professor Bruns' clinic at Tübingen. It is the parenchymatous injection of iodoform in a solution of ether and olive oil, the proportions being seven grammes each of olive oil and ether and one gramme of iodoform. Under this treatment the measurements of the enlarged gland are diminishing rapidly. Garé published the clinical records of twenty-five to thirty cases in which this method was carried out with exceedingly gratifying results. I am speaking, however, only of the hypertrophic form.

DR. WM. J. TAYLOR asked if Dr. Roberts had noticed any especial respiratory difficulty or nervous shock in his operations when working near the sheath of the vessels of the neck or in deep dissection. In two cases coming under his observation which were being operated upon for goitre, everything seemed to be going on well, when suddenly during the dissection, in which there had been no hemorrhage of any account, the patient had some respiratory difficulty and rapidly sank, dying in a few hours without any obvious reason.

DR. G. G. DAVIS: There are cases of goitre in which the tumor is not very deeply seated and does not go below the sternum and great vessels, so that it can be easily shelled out, and the hemorrhage is almost *nil*. In other cases the hemorrhage is very marked. I saw one case where the patient died upon the table from it. This happened in the hands of a surgeon of highest skill. Therefore I think that the seriousness of an operation depends upon the kind of case it is rather than the operation or the surgeon, and

accidents might happen in the hands of any one.

DR. SHOEMAKER: I was present at one of the operations reported, and was very much pleased with the skill of Dr. Roberts in managing the hemorrhage by carefully securing the bleeding vessels. It was one of those thyroids which are not very adherent, and did not descend much below the border of the sternum. The special point of interest to me was in seeing how easily such growths come out when skillfully attacked.

DR. DAVIS: If these were cases of intracapsular enucleation I would be much interested in hearing about the bleeding and how it was controlled. The substance of the thyroid gland and veins in these cases is so extremely friable that it is almost impossible to control the bleeding by the application of hemostats. They simply tear out; they will not hold at all. Dr. Wolff, of Germany, advocated the intracapsular enucleation of the enlarged thyroid gland, and the method he recommended was practically to bite away the growth piecemeal, controlling hemorrhage as you go along by means of pressure. It takes exceedingly skillful manipulation to perform a thyroidectomy without hemorrhage by such a method, and most of the other surgeons who discussed his paper preferred the ordinary method of Kocher.

DR. ROBERTS: I did not work inside the capsule, but principally outside. I cut down outside of the capsule and shelled out the tumor. The operation was extracapsular except where the capsule was accidentally cut through during the operation. Of course, the goitres are much less large with us than the goitres seen in Europe. In the greatly enlarged glands the vessels are increased in number and size, as well as the tissue elements. I have seen a comparatively large number of goitres at the Woman's Hospital, and I have refused to operate upon a good many of them. It seems to me, however, that where there is dyspnœa or pain from pressure upon the vessels or the nerves by the growth it is proper to operate. In many cases relief can be obtained by medicine, and if we can succeed in taking the patient's mind off from the goitre the enlarged gland will give less trouble. The cases reported, it appears to me, were proper ones for operation. With regard to Dr. Taylor's question, I have seen profound collapse during an operation upon the neck, although not in a case of goitre. There was sudden stoppage of breathing and serious circulatory disturbance. I found that I was making pressure upon the pneumogastric nerve; as soon as I relaxed it the breathing became normal.

Dr. Muehleck presented

A REPORT OF FOUR CASES OF DIPHTHERIA TREATED BY ANTITOXINE.

(See page 756.)

DISCUSSION.

DR. H. A. HARE: I had the honor of being invited to be present at the Municipal Hospital when the inoculations were made by Dr. Fischer, of New York; but think that I have very little to add to the report of Dr. Muehleck. There are, however, several things which impressed me very forcibly at the time of making these experiments, which I have not had time to clear up. One was that the cases were desperate ones, fairly rotten with sepsis; you could scarcely believe it possible that children could survive such profound poisoning. Some of them were simply gasping for air, not from obstruction but from prostration of the vital powers. Some had as much as 60 per cent. of albumin in the urine, the pulse was indistinct and could scarcely be found at the wrist; while the most careful auscultation was needed to distinguish the heart-sounds. Such cases were among those that received the injections, as I have said. What the result is it is too soon to say, but I was impressed with the thought that the test in these cases could only end in failure. If the treatment could be given at an early stage, before the kidneys, the heart and the other important organs had become so seriously involved, it may be useful. Dr. Fischer thought the cases desperate, but declared that the severe cases were the most favorable for the test. In one case he used an Aronson's solution, which was three times as strong as Behring's. I believe that one of the patients who received the antitoxine is still alive and in about the same condition; the other case I have not heard from.

Now if, as we all believe, diphtheria is primarily a local disease caused by infec-

tion with the bacillus whose growth causes the development of toxine, I am free to confess that I would rather take my chances with the toxine than to inject any amount of immunizing serum into my blood. The child has not only to struggle against the toxine of the Klebs-Loeffler bacillus, but also the toxines of the other bacilli, which cause so-called pseudo-diphtheria, and of the ordinary bacteria of inflammation and suppuration, and the use of antitoxine may, for all we know, increase the strain on the organism.

Dr. Carl Frese, from the German Hospital, by invitation, gave his experience with antitoxine. He said: I received some serum from Charles H. Meyer, German Consul in Philadelphia, directly from Behring. The first case it was tried upon was a case of Dr. Woodward's. It was in a family where three were attacked by diphtheria. The second case was the only one in which it was tried. The child was in a desperate condition and died three hours after the injection. We made cultures and found the Klebs-Loeffler bacillus, also staphylococci and streptococci. The third child was just beginning to get sick, and nothing was seen in the throat of false membrane. In that case the child had been exposed to the infection. We used one-tenth of a bottle of the antitoxine, and the patient got well of her malaise without developing any membrane. Another case at the Municipal Hospital, by invitation of Dr. Welch, was very bad the fifth day of the disease, and he said that from his experience it would die. We gave it an injection of 1,000 normal units of the antitoxine, and the child is living yet, a week afterward. The last report was that the child was doing better, but the pulse was still weak. Another child, who had been brought in on the same day, he thought might not recover under ordinary treatment. This case was also treated with antitoxine and recovered. The mucus from the throat of each of the children was examined and found to contain the Klebs-Loeffler bacilli.

Dr. Edwin Rosenthal: There is nothing that interests me as much as the therapy of diphtheria; and it was with peculiar care that I followed the experiments of Dr. Muehleck as he described them to me, with their satisfactory results. In the statistics presented this evening on the treatment of diphtheria by antitoxine, the greatest proportion of recoveries was shown in cases where the treatment began on the first day of the disease. These statistics were classified peculiarly, and had reference to the number of days the patients were ill before the treatment was begun, as the first, second, third and fourth day of the disease. They had no reference to the gravity of the disease nor the complications. As such their value must in some way be diminished, for we all know that cases of diphtheria seen early enough can be so treated that the infection becomes modified and recoveries be the rule. For this reason the old method of treatment might be classed as equally good; and many a physician, notably my friend Dr. A. Klein, who has seen many cases of diphtheria, has a record of no deaths. I should believe that in those desperate cases —such a one as described by Dr. Hare—the real efficiency of antitoxine can be tested. But, nevertheless, the cases reported by Dr. Muehleck this evening have proved that its use prevents the full development of the disease, and if developed improves the gravity of the symptoms to a remarkable extent.

Regarding the statistics of the cases upon which tracheotomy was performed, I, for myself, cannot see anything remarkable, as I think the statistics of Dr. Wharton with the present plan of treatment equally as good; however, if with one or more injections of antitoxine the course of such cases can be shortened, we have assuredly a good remedy. In Dr. Muehleck's paper no mention was made of those cases of laryngeal diphtheria intubated and treated by antitoxine. All the statistics I have seen on this special subject have recorded no deaths—surely a record which places antitoxine foremost as a remedy. The first case in which Dr. Muehleck used the injections was one of laryngeal diphtheria, and I was present when he made his first injection, using the serum of Aronson, manufactured by Schering. Though the stenosis was marked, intubation was not practiced; and on the second night, when suffocation appeared imminent, Dr. Muehleck, at the suggestion of Dr. Klein, still postponed intubation, but gave a second injection; and this case recovered. This recovery was deemed by Dr. Muehleck due to the employment of

the remedy, for no other special means was employed; surely another demonstration proving its efficacy.

Last June I wrote to Sanitäls Rath, Dr. A. Baer, of Berlin, for some antitoxine. His position is such that it gives him peculiar opportunities to be well posted in sanitary matters. Through him, on a former occasion, I was enabled to receive a supply of Koch's tuberculine, and probably the result of those experiments prompted him to write me to wait further development. On the 2d of October I received a letter from him in which he wrote me that the excellent monographs presented at the International Hygienic Congress at Pest and the Naturwissenschaftliche Versammlung at Vienna have pronounced in favor of the antitoxine, so its usefulness may be regarded as established.

DR. A. KLEIN: The cases referred to by the last speaker were mostly mild cases and would have recovered under any ordinary treatment. The cases I have seen with Dr. Muehleck were of a different type entirely. In the first one, stenosis was so marked that intubation or tracheotomy was considered, but in order to give the antitoxine a fair trial we decided to give a second injection and to wait with surgical interference till the symptoms would grow more urgent. The case as reported got well.

In addition to the statistics referred to to-night which are in favor of antitoxine, I would mention 35 cases treated by Dr. Bokai in Budapest with antitoxine *exclusively*, of which 19 were of the most severe type; 16 of them had to be intubated. Of the 35 cases 8 died; of the intubated ones all recovered.

The *Medical News* (November 17, 1894) reports another case of diphtheria of the most severe type, with extensive membranous deposits all over the pharynx, treated with antitoxine by Dr. Catlin, of Brooklyn, which recovered. In this case the Klebs-Loeffler bacillus was found twenty-one days after the recovery.

DR. D. BRADEN KYLE: I can add nothing to the observations already stated as to the clinical effects of antitoxine, but I might add something in regard to the examination of cases for the bacilli. What has been said in regard to the presence of other organisms is quite true. In all the cases I have studied where streptococci were present the case was more malignant than if the staphylococci were found; as a rule, many germs are present besides the Klebs-Loeffler bacillus. The germ of false diphtheria (von Hoffmann's) is so much like the germ of true diphtheria that it may be necessary to resort to the inoculation of animals to make the diagnosis. Inoculations made on blood-serum and incubated, the first growth to appear on the surface of the serum is, as a rule, the Klebs-Loeffler, and in most cases the diagnosis can be based on stains from these growths; only in the older cultures is there any marked difference.

The serum of Aronson is of several strengths: one preparation labeled diphtheria antitoxine is not intended for treatment of diphtheria, but for the purpose of immunization. At the request of Dr. Morton I have with me a number of microscopic slides showing the germs from tubes eighteen hours after inoculation and also from older growth, from which the marked variance in form can be observed. These are now ready for examination.

DR. T. XAINE: With regard to the so-called pseudo-bacillus I would remark that some German pathologists deny that there is any difference. Some French authorities, on the other hand, affirm that there is a distinction, that the pseudo-bacillus is shorter and grows more rapidly in cultured media. It is also asserted that it may be found in the throat during perfect health, and in the throats of individuals living in communities where there never had been diphtheria. It is said that the pseudo-bacillus is found in 15 or 20 per cent. of healthy children, and that the virulent bacillus may lose its virulence, but by culture in suitable media this may be restored. Four days ago I injected into the trachea of a rabbit 1 c.c. of a solution of the Klebs-Loeffler bacillus bouillon culture. The rabbit had symptoms of dyspnœa yesterday. He had a beautiful membrane throughout the larynx down to the bifurcation of the trachea. On making cultures of the bacilli I found that they had regained their virulence and former thickness. I think that in New York they do not recognize any distinction between the true and false diphtheritic bacillus, and consider them all as diphtheria germs. I think that Dr. Abbott also does not believe that there is any difference between the true and false diph-

theria bacillus. As regards streptococci and staphylococci, they are always found in the mouth and their presence only indicates a double infection.

DR. MUEHLECK: I think that every experienced physician will agree with me that there are very few chapters in medicine more disappointing than the treatment of diphtheria. In fact, the treatment until now has amounted to very little, it being always a question, in my mind, whether the patient was not more injured than benefited by the attempt to make applications of disinfecting solutions to the throat in a struggling child with a weak heart. The results from surgery have been even more desperate. Anything, therefore, that will afford a ray of hope should be welcomed with delight. The cases I have seen are too few for conclusive opinion, but the results from Europe are very favorable. Virchow, who is usually very conservative in such matters, has indorsed this treatment. The prognosis depends largely upon the day of the disease when the treatment is begun, as I have already said in my paper. Behring and Prudden have shown that sepsis by streptococcus invasion is common in the later stage of the disease. The formula distinctly states that the antitoxine is powerless against such infection.

AUTO-INFECTION.

The subject of auto-infection is one which the physician may study with great profit, both to himself and to his patients. It is the direct offspring of bacteriology, but is not, by any means, the first time error has given birth to truth.

By auto-infection we mean the pathological manifestations brought about by the formation and retention of poisons within the system; and to thoroughly understand the subject we find necessary a knowledge of the normal chemistry and physiology of the body.

In perfect health a certain percentage of poisonous excreta is formed, and this the organism can safely dispose of within certain limits; but when, through unhygienic living, this percentage is daily increased, the depurative and eliminating organs become paralyzed and later diseased through overwork, and we have the supervention of various pathological phenomena from the accumulation of poisons in the system.

Thus it is with Bright's disease. A man appears in fair health. He is attending to his business and seldom complains. His blood contains more than the normal percentage of poisons; his liver and kidneys have been laboring for the past year or more to discharge this additional work; they are almost exhausted and the man is in the position of a boiler about to explode. He has had some warning because nature is just, although severe.

He has had frequent dyspeptic attacks to which he paid no heed; he has suffered from violent headaches, painful vision; he is breathless upon slight exertion, his heart wobbles uncomfortably; his hair has begun to fall, perhaps, but what of it? He is forty-five or fifty years of age and these are the inevitable, if unpleasant, concomitants of coming age.

And so the explosion comes. Monday he is seen on the street; Saturday he is dead. The physicians assure the grief-stricken family and friends that the disease had been coming on a year or more and had gone beyond medical aid; that had he consulted them earlier he might have been saved.

This is poor consolation, but it is true. Doctor, educate your patients, educate yourself. Teach them to come to you early before a disease has gone beyond the resources of medicine, and study the subject of auto-infection to its utmost ramifications; you will find in it the source of two-thirds of the diseases, if not all. Its manifestations will vary with the nature of the poison, its quantity, the age, condition, vital resistance of the patient, etc., and the chief problem will be to ascertain the influential factors in each individual case.

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

Growing Pains.

Growing pains, defined as pains in the limbs caused by and during rapid growth and sometimes so severe as to give rise to growing fever, have been diagnosed by the author less and less frequently as the years rolled by, until the vanishing-point was reached. Cases which have been classed together under this name are the following:

Myalgia from Fatigue.—This is the commonest variety, usually about the knees and ankles after unusual exertion. They are probably due to auto-infection brought about by excessive production of *effete* materials in the blood and their inefficient elimination. Elevating the limbs and rubbing with the palm of the hand in a direction toward the heart, relieving venous stasis and facilitating a supply of healthy blood to the exhausted muscles, promptly relieves the pain.

Rheumatism.—This is second, if not first, in frequency. There is slight pain in the joints, little or no swelling, and very mild fever, and hence the true cause is not recognized; but rheumatic endocarditis frequently develops in these cases.

Diseases of Joints and Bones of the Lower Extremities.—Cases of hip-joint disease and suppurative epiphysitis of the upper end of the fibula, diagnosed by the laity and allowed to go on untreated, are related under this heading.

Fevers, accompanied by pains in the limbs, in one instance proving to be inception of typhoid fever, constitute this class.

Adenitis.—Here, again, the mother still supposes that the lad of sixteen years suffered from "growing pains," but he was treated for gonorrhœa and a sympathetic bubo.

The malady "growing pains," with its frequent concomitant growing fever, like its congener disorders of dentition, as a separate morbid entity exists principally as an article of faith. The complaint still maintains, however, a strong hold of the lay mind, and forms an extremely common lay diagnosis which is often the cause of much suffering, and even death, by leading to the neglect of curative measures at a time when they are most effective.—*P. B. Bennie in Arch. Pediatrics.*

Neebe's Treatment of Sweating Feet by Crude Hydrochloric Acid.

When the feet are very tender, especially in hot weather, treatment is preceded by an eight to ten days' application of talc powder, which is sprinkled in the stockings. The application of the acid is made in the evening. The crude hydrochloric acid is poured into a flat vessel of stone or glass or porcelain sufficiently large to receive the two feet. Since the soles of the feet and the skin between the toes are the seat of the trouble, sufficient hydrochloric acid is poured into the vessel to completely cover the soles. It should not be allowed to come in contact with the skin of the back of the feet. The heel is kept in the acid for five minutes; then the sole of the foot for ten minutes. After this the feet, especially the skin between the toes, are washed in soap and warm water. Soaking in the acid must be at once stopped as soon as pain is excited, and the painful spots must be treated with zinc ointment until healing is complete. The process of soaking may be repeated twice weekly, and continued for from five to eight weeks in obstinate cases.—*Med. Press and Circular.*

Treatment of Croupous Pneumonia.

Kiad, in a paper published in *The Practitioner*, confines his remarks to two remedies—opium and strychnine. He says that to him the only definite contraindication to the use of opium is furnished by symptoms of impending exhaustion of the respiratory center—shallow, labored respiration, drowsiness and a tendency to cyanosis. While not a drug to prescribe in a routine way, it is not denied that excellent results may be adduced in favor of such a practice. The chief indications for giving opium, with the reservation just mentioned, seems to be severe pain that cannot be controlled by other measures, insomnia, restlessness and delirium. While it is not claimed that these symptoms should always be treated by opium, they may be often effectually and always safely so treated at any stage of the disease. The drug is generally best given in one full dose at bedtime—say 10 grains of Dover's powder or $\frac{1}{4}$ to $\frac{1}{2}$ grain of morphine hypodermatically. Under this treatment, which was in some cases continued from the beginning of the attack to the crisis, the number of respirations was generally reduced by ten or twelve in the minute, the pulse being either unaffected or exhibiting a transitory reduction in the number of beats. No marked effect on the expectoration could be traced. In the use of strychnine he supports the views of Habershon, who holds that its efficacy is due to its action being exerted on the excito-motor-nerve apparatus of the heart and on the respiratory center. The action of strychnine brings indirect support to the view that in pneumonia what we have to fear is the influence of toxines on the nervous system. On this hypothesis cardiac failure is only an expression of exhaustion of the nerve centers and is therefore an indirect effect of the poison. It is best given hypodermatically directly into the gluteal muscles in doses of $\frac{1}{60}$ grain, the indications for its use being derived from the pulse. If the tension begins to sink or if the

frequency of the beats is much increased, it should be tried at once. Its good effect on the pulse and the respiration is often manifested in ten or fifteen minutes. When the rally is not maintained the above dose may be repeated every two hours until three or four doses have been given, and then o nce or twice in the twenty-four hours until the pulse and respiration right themselves. In the treatment of delirium strychnine often acst more beneficially than alcoholic stimulation.

PATHOLOGY.

Clinical Value of Renal Casts.

Many clinicians can recognize casts under the microscope but fail to interpret their significance. Dr. A. E. Austin, in the *International Medical Magazine*, separates them into definite groups and draws inferences accordingly. The hyaline and blood casts merely indicate irritation and hyperemia. Closely associated with hyaline casts is amyloid change of the kidney due usually to suppuration and with a good prognosis if the source of suppuration be removed. Epithelial, granular and fibrinous casts indicate acute inflammation of the renal tubules, the epithelial cast pointing to the mild stage; that is, one of mere desquamation with urine slightly under normal in amount, specific gravity 1030, high color, albumen a trace, numerous hyaline casts, free blood and renal epithelium. This may go on to brown or pale granular casts with diminution of the solids of the urine. The fatty and waxy casts when numerous and persistent indicate long-continued chronic inflammation of the kidney with bad prognosis. Blood and epithelial cells are absent. In this case the urine is diminished in amount with increased specific gravity. The pale, granular and small hyaline casts point to fibroid kidney. Aside from the microscopical appearance, the general condition of the patient, age, sex and previous history must be taken into consideration. It should be remembered that the diagnosis of casts alone may mean little, but the kind of casts in abundance is the important point.

The Causes of Narcosis-Paralysis.

Under the name narcosis-paralysis, or pressure-paralysis, the Germans group those cases which occur after narcosis, or long-continued lying in one position. Primary cause: They occur most frequently in the arm after operations, during which the limb has been kept elevated for long at a time. Braun has considered them to be due chiefly to the clavicle pressing the brachial plexus against the vertebral column, and to the direct pressure of the head of the humerus on the nerves. More recently Gaup (*Centralblatt f. Chirurgie*) has claimed that the nerves are compressed between the clavicle and the first rib; possibly also, in certain cases, between the clavicle and the scalenus muscle. In any event, the occurrence of these cases is a warning not to keep the limbs in constrained positions any longer than is necessary during operations. Pernice reports a case where a paralysis of the radial nerve, lasting, unimproved, till the patient's death (three weeks), occurred, probably from the forearm happening to lie against the edge of the table at the point where the nerve turns around it.

Menstruation and Infection.

The connection between erysipelas and infectious peritonitis has long been considered intimate, and there is now good ground for the belief that from a bacteriological point of view the two diseases are identical. In the *Presse medicale* for September 29th there is an interesting communication from Dr. Henri Meunier, a hospital interne, giving an account of a fatal case of peritonitis which suddenly attacked a healthy young girl under somewhat peculiar circumstances. She was a domestic servant, and her mistress was seized with severe facial erysipelas. The young girl took an active part in nursing the sick lady, was almost constantly at her bedside, and personally attended to changing the applications to her face. While this was going on the girl's menstrual flow appeared and she committed the imprudence of using as a menstruous napkin a cloth that had been used in a dressing for the lady's face. She was suddenly seized with a violent chill while out for a walk, also with malaise, head ache, general depression, and soon repeated vomiting. Her courses, which had appeared two days before, were brusquely suppressed. Her death followed in the course of five days, and the post-mortem examination showed conclusively that the disease could have had no other origin than by infection from the napkin. The case is recorded with all the details, and the author's remarks on it are well worth reading in full.

DIETETICS.

Home-Made Beef-Powder and How to Prepare It.

Dr. William R. Huggard (Davos Platz, Switzerland) writes in the *British Medical Journal:* Some of the beef powders in the market smell and taste of the chemist's shop, and are not readily taken by an invalid whose palate requires to be coaxed. A happy idea struck the writer several months ago that beef-powder might without difficulty be prepared fresh and on a small scale by any ordinary cook. The experiment was made, and the result was satisfactory beyond expectation. Beef-powder made at home is appetizing, has a delicate aroma and flavor, and can be taken with pleasure by invalids who turn with aversion from ordinary food. If a little pepsin be taken at the same time, it is digested even when the ordinary peptonized foods are not retained.

The mode of preparation is simple. Lean beef is cut into small pieces; these are put into boiling fat, dripping, or butter for a couple of minutes until the surface is browned. They are then removed from the fat and placed on a strainer for a few moments. Afterward they are placed in a mincing-machine. The resulting mince is placed in a slow oven and dried. The drying process may take from five to twenty-four hours, or even longer, according to the heat employed. When thoroughly dried the meat is quite crisp, and can be ground in a coffee-mill that has not been used for any other purpose. In the drying process the meat loses a trifle more than four-fifths of its weight. This beef-powder can be taken in various ways—with hot water or soup, with mashed potatoes, with bread and butter in a sandwich, or with a little pepsin in a starch wafer. The writer has given this home-made beef-powder with such excellent effect in several cases where there was much difficulty with food that he thinks others may find it useful.

Beef-powder, carefully prepared according to the directions above given, has an agreeable flavor, and admits of being used like potted meat by persons of delicate or fanciful appetite. By regulating the heat applied in making the powder the albuminous constituents need not be coagulated, but merely dried, and the digestibility of the powder would then be increased; in any case, the finely divided condition would facilitate digestion. A very good beef-tea may be made from the powder by infusing it in moderately hot water. For the preservation of the powder it would be necessary to keep it from contact with atmospheric air and to avoid the access of mites or similar deteriorating influences.

Boiled Milk as an Aliment Abroad.

The practice of subjecting milk to boiling heat before consumption has been widely adopted in European countries, whose public hygiene has hitherto been such as to counsel every means of minimizing the conveyance of infection. British travelers, in Latin countries especially, will be reassured by this salutary innovation, experience having taught them that the milk supplied in hotels and pensions and added to their morning meal of tea and coffee has too often been tainted with the micro-organisms of infectious or contagious disease, chiefly from being diluted with impure water, not seldom containing the desquamatory *debris* of convalescents from scarlet fever. Sanitary truth progresses slowly into these regions, and when the public health officer at length succeeded in establishing the unwelcome fact that milk was one of the surest channels by which infectious diseases were diffused, he had to encounter the objection that the boiling process to which he insisted on its being subjected deprives it of its nutrient properties and also its digestibility. Again, however, he has been able to show that reason was on his side, and that milk after boiling is not only more easily digested, but has actually a higher nutrient value than in the crude state. We allude especially to Dr. Chamouin's experiments, in which he fed a number of kittens on boiled milk and an equal number of kittens on the same milk as it came direct from the cow or goat. Those of the former category he found to be twice as fat and healthy as those of the latter. Following up this demonstration, Dr. Chamouin examined the statistics officially issued by the town council of Paris as to the infantile mortality of that city, and finding that the chief cause of this was, directly or remotely, intestinal ailments, he prosecuted his researches still further, so as to include a comparison between those infants that had been fed on boiled and those that had been fed on unboiled milk. As he anticipated, he found a remarkable diminution in the death-rate of the former. His investigation was continued long enough to show that thousands of infants are annually safeguarded from intestinal disease and death by the precaution of boiling the milk on which they are fed.—*London Lancet.*

SURGERY.

Sterilization of Catgut by Boiling in Olive Oil.

Eastman (*Annals of Surgery*) experimented with the sterilization of catgut by means of hot olive oil. The following are his conclusions: Catgut can be rendered sterile by heating in oil to a temperature of 212° F. for three hours. The method is reliable, cheap and rapid. The quality is not impaired, and gut so treated is more satisfactory as to strength and smoothness than if subjected to the ether-alcohol-bichloride precess. A higher temperature than 212° F. is not necessary for sterilization and is an injury to the gut. The material should be wound on reels or cylinders and not on anything with sharp edges.

Antipyrin as a Vesical Analgesic.

Vigneron (*Annales des Maladies des Organes Genito-Urinaires*) is convinced from its employment in three cases that antipyrin will prove to be a valuable vesical analgesic. Injected into the bladder the remedy is free from harmful effects, even when employed over a protracted period. As an antiseptic the author believes it to be superior to solutions of boric acid. When the solution of antipyrin is allowed to remain in the bladder, it not only relieves the pain but checks spasmodic contractions. A 4 per cent. solution left in the bladder for ten minutes is sufficient to diminish the pain attending subsequent washing or instillation. Antipyrin may be employed in all cases of cystitis in which local treatment induces pain. When the bladder is not distended, two and a half to five drachms of a 4 per cent. solution, left in the bladder for ten minutes, is sufficient. When the bladder is much distended, fifteen to thirty drachms of a 1 or ½ per cent. solution should be injected and allowed to remain in the bladder.

HYGIENE.

The Nose and Its Hygienic Relation to the Body.

It is no unusual thing to give advice to our fellow-man. To prevent his doing what he is impelled to do by force of nature or of habit, without showing him a better or, rather, the true way of relief, is virtually improper. In this connection the following is suggested: Each human being who claims any moderate amount of cleanliness and care regarding his health will, during his morning ablutions, wash his face, head, mouth, teeth and body, and may do so without ever dreaming that the human proboscis is one of the most uncleanly organs of the body (which fact our forefathers sought to overcome by the use of snuff, etc., but which proved of no avail), and its purification lies, last but not least, in washing the nostrils proper, and this should be done in the following way:

After the completion of the above ablutions and the thorough renovation of the basin used, fill it nearly full of pure cold water; immerse the whole face therein, and by trial learn how to gently snuff water as one would customarily breathe air; a few sniffs may be taken and the face withdrawn if the taking of breath has become necessary, and again immersing the face, repeat the action several times, but mark you, no force must be used. The result will speak for itself in the residue left in the basin, thus proving the necessity for removing the surplus secretions of this organ and avoiding the dangerous necessity of carrying your catarrhal as well as tuberculoid matter in your pocket, not mentioning the sometime contagious results from the laundering of handkerchiefs. The mucous surfaces of the nose thus become accustomed to the influence of the daily temperature by using the water in its normal condition, and many years of practical experience by its disciples has fully demonstrated the efficiency of this system.

All persons subject to catarrh who practically have dry and clear nostrils nevertheless have mucal droppings into the throat, and are often involuntarily compelled to swallow this retroverted mucus.

All this can easily be overcome by the permanent adoption of this system of cleanliness. The strong snuffing up and down of water in the nostrils is too forcible for that sensitive organ of smell, and no nasal douche should ever be used for the same reason. The above gentle flushing system is confidently urged as the most efficient and least harmful method of cleansing the nostrils.—*Herald of Health.*

PHYSIOLOGY.

Anti-Toxic Action of the Liver.

It has been established for some time, says the London *Lancet*, that the liver has a power of retaining certain poisonous alkaloids in high proportion and in their most active state when injected into the circulation. Dr. Schupfer, of the University of Rome, Italy, has now shown by experiments on frogs that by intrinsic action due to the specific activity of its cellules the organ diminishes the toxic power of the alkaloids with which it is brought in contact, not only those introduced from without, but those elaborated within the body, as from disease. The importance of a normally working liver is thus more apparent than ever.

OBSTETRICS.

Treatment of Early Abortion.

A conservative treatment of early abortion is recommended by Schauta, of Vienna, in a recent article. The old rule that pain and hemorrhage combined mean inevitable abortion he does not indorse, and thinks the accident preventable as long as the hemorrhage is not excessive or the cervix dilated. He does not try to check the bleeding and trusts to rest, which is continued for eight days after the last bleeding. In those cases where the os dilates and abortion becomes inevitable, he tampons with a strip of iodoform gauze about two yards long and the width of three or four fingers' breadth. He prefers to retract the perineum with the fingers of the other hand instead of using the speculum, and renews the tampon at the end of twenty-four hours at the least, removing it sooner if the appearance of sacral pains indicates that the ovum has been expelled from the womb. This method of treatment is in sharp contrast to the radical advice so often given of late to go in at once and curette out the womb as soon as an abortion becomes inevitable—a practice which Schauta objects to because of the danger of leaving fragments of membrane behind.—*Western Lancet.*

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM NOVEMBER 18, 1894, TO NOVEMBER 24, 1894.

The leave of absence granted Captain Adrian S. Polhemus, Assistant Surgeon, is changed to leave of absence on account of sickness, and is further extended to include December 26, 1894, on surgeon's certificate of disability.

NEWS AND MISCELLANY.

Routes and Rates to Winter Resorts.

The B. & O.R. R. Co. has just issued a little booklet giving the routes and rates to various winter resorts in Cuba, Florida, North Carolina, Virginia, New Jersey, Pennsylvania and Georgia. The information is very conveniently arranged and indexed. Copies can be had by inclosing a two-cent stamp to Chas. O. Scull, Gen'l Pass. Agent B. & O. R. R., Baltimore, Md.—2t

ORIGINAL ARTICLES.

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., New York.

[CONTINUED FROM PAGE 750.]

The integumental investment of the abdomen anteriorly is thin and elastic, freely movable and resistant. As its antero-lateral areas are without solid osseous underlying supports, in the application of force the capillaries escape rupture, so that discoloration or ecchymosis, so commonly following contusion elsewhere over bony surfaces, is generally absent in this locality. With the body in the recumbent position, the antero-lateral walls being composed of yielding material, on pressure being applied here they can be forced backward or inward until arrested by the central osseous ridge of the spine. But with the body lying prone on the face and chest, as but a very limited area of the abdominal boundaries is at all exposed, and this is so powerfully protected by the spinal muscles and the lumbar vertebræ, vulnerant force must be great and concentrated to produce disorganizing effects on the abdominal viscera in this direction.

It is well to observe, also, that when a heavy substance is brought to bear on the lumbar region, the body resting prone on its anterior areas, concussive pressure is transmitted through the back and is partly spent on the thorax and pelvis.

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

FIRST CLASS.

Concussive and Compressive Injuries of the Abdomen, Moderate or Superficial.

The comparative frequency of injury of the various structures and organs of the abdomen will depend on, first, their exposed situation; second, their composition; and, third, the manner in which force is applied.

THE ABDOMINAL WALLS.

Integument.—The structures which enter into the protecting walls of the abdomen and are the first to receive the impact of violence, as we would expect, are those most often implicated by injury. The most marked exception to this rule is the integumental envelope, which extends from the ensiform cartilage to the crest of the pubis and Poupart's ligament, and as far laterally on each side to the outer edge as the lineæ semilunares. Here the skin is thinner than anywhere else in the body, but its mobility and resistance are such that rupture of its capillaries and consecutive ecchymosis are scarcely ever seen, even with very extensive damage to their parts

underneath. The same peculiarity attaches to the skin covering the five lower ribs, and though costal contusion or fracture may occur, ecchymosis seldom appears in many cases until reparative processes are advanced. But over either lateral plane of the lumbar region and laterally over the lumbar fascia and oblique muscles, as far forward as where their fibers terminate in an aponeurosis, vascular effusion into the integument, with ultimate free staining of it, is a common event.

THE MUSCLES.

Striped muscular tissue in every region of the body offers remarkable resistance to trauma, and in none is this quality more manifest than in that which supports and maintains the abdominal contents.

Although some authors maintain that contusions of the abdominal muscles are an uncommon event, my own experience has been to the contrary. The lesions here, of a superficial character, in their order of frequency and importance are:

1st. Simple contusion, with or without sanguinous infiltration.

2d. Sprain.

3d. Laceration or rupture of muscle.

Simple contusions are caused by moderate blows or falls over any of the abdominal areas. Moderate soreness and tenderness follow, which pass away after a few days, as a general rule, without any constitutional disturbances. But when the force is moderately severe and falls are sustained over the ribs which enter into thoracic wings, a most painful and protracted intercostal neuralgia may follow, which is aggravated by motion, inspiration, or any spasmodic action of the diaphragm. The pain and tedium succeeding moderate concussive force applied here probably results from injury to the intercostal nerves. But in time it passes off without leaving any pathological changes in the affected parts.

Sprain or rupture of the abdominal muscles follows a sudden violent stretching of them. Such tension may occur from direct pressure, as when one is caught by some compressing agent, usually either over the hypogastrium or over the lateral lumbar muscles.

For obvious reasons we can understand how an uncomplicated sprain is seldom seen over other areas of the abdomen. In severe sprains the aponeurotic investment of the muscle or even some of its fibers may give way.

These are most often encountered in the lumbar region, and here generally occur in consequence of a sudden lateral inclination of the spine, the affected muscles being subjected to violent tension.

A severe muscular strain is always followed by a distraint and painful lameness in the affected parts, which is slow in being recovered from, though as a rule full functional power, after a time, is reëstablished. Rupture of a muscle with retraction of its ends I have never seen over any part of the abdominal walls, except where mortal injury was associated with it. The rectus is the most exposed to this lesion, and cases are on record in which rupture of it occurred by spasmodic contraction alone.

It is possible certainly that a muscle may be partly or even wholly ruptured without detection. For example, in those whose abdominal muscles are masked by deep layers of fat or when the muscle ruptures within its sheath, when the interspace is slight, and when there is no hernia of its fibers through its thecal envelope. Inasmuch as no case of uncomplicated muscular rupture over the abdominal areas has come under my notice since my practice brought me in frequent contact with traumatic cases, and more than five thousand of various descriptions of traumatism have been examined by me, I am disposed to believe that it is a very unusual complication.

THE APONEUROSIS.

The flat, broad tendon of the external oblique turns on itself below, and with its fellow of the opposite side constitutes the center of attachment, particularly of all the muscles lying over the anterior plane of the abdomen, except at the crest of the pubis, wherein the recti are inserted, and a plaque of the external oblique contributes to the formation of Gimbernat's ligament.

Tendinous structures possess greater resisting power to violence than the muscle, as we observe in injuries of the extremities, when muscles will rupture from violent spasm, or the tendon may drag away the very bone surface into which it is inserted before it will give way itself. As we will see later where contusion of the central organs is considered, the areas of the abdomen covered in

chiefly by aponeurosis are by no means the weakest.

Many attribute their hernial infirmities to blows or falls sustained some time in life over the inguinal areas. In fact, a common impression prevails that this is their usual origin. This is not surprising when we recall to mind the popular term *rupture*, which is applied to hernia and even yet persistently employed by various modern authors.

But in an inguinal hernia there is nothing ruptured or torn, nor does hernia probably ever arise in consequence of blows or falls over the inguinal region. Of this I am assured from an examination of many who have sustained blows over the inguinal region. Nevertheless, if the injured has had hernia in infancy or is the subject of one in the process of growth, there can be no question but violence may hasten its development or impart serious features to it.

SECOND CLASS.

Concussive and Compressive Injuries of the Abdomen, Central and Serious.

While peripheral trauma of the abdomen is not uncommon, deep or central is met with sufficiently often, and is so grave in its consequences as to warrant a careful consideration of it. This is particularly opportune at the present, since aggressive surgery has essayed to treat many visceral lesions of the abdomen by direct intervention. It has been quite generally conceded that operative surgery at present in many pathological conditions within the abdomen is a means more effective in prolonging and saving life than the more conservative constitutional measures in vogue before the time when anesthetics, antiseptics and experimental studies had made it a permissible procedure to open the abdomen in the living subject.

How far similar radical surgical procedures may be utilized in those contusive injuries associated with the laceration or rupture of the organs, it is highly important to determine.

Quality of Physical Force in Crushing Lesions of the Abdominal Organs.

The above may be divided into two varieties:

1. Percussive or concussive.
2. Compressive.

Percussive or concussive force is an etiological factor of great importance in many injuries to the deep viscera, and especially to the solar plexus. The abdomen may sustain the impact of a quickly moving body, as a ball thrown with great impetus, an arrow, a spent missile, or in fact any projectile moving with great velocity, which may reduce a solid viscus to a pulp, rupture the intestine or widely open the vascular structures, and yet leave no trace of injury at the point where it struck the integument.

Thus in one case that came under my care in hospital nine years ago, a burglar was fired on by a policeman as he was escaping through a window. The shots were fired from a thirty-two-caliber revolver at a range of about thirty feet.

After the second shot the burglar fell back into the room. He was immediately sent into the hospital. He was seen by me three hours later. He was now in mortal shock and incessantly groaned from pain in the abdomen. On examination it was discovered that he had apparently been shot in but one place. This was through the convexity of the deltoid, the ball passing completely out. But his urgent symptoms were abdominal. Here, however, there was no discoloration to indicate contusion, though on examination it was evident that he had a large internal hemorrhage. He died six hours after admission. On post-mortem examination the cœliac axis was found widely opened and the jejunum was nearly torn in two just where it emerged at the left under the cardiac end of the stomach.

The cavity of the peritoneum was flooded with blood and intestinal contents.

The sympathetic ganglia and solar plexus receive many communicating filaments from the vagus and the internal terminals of the anterior division of the spinal nerves from the lower dorsal region of the cord.

This may perhaps partly explain why a sudden severe blow over the epigastrium produces such an impression over the cardiac and respiratory centers. There are few males who pass through life that have not experienced that sensation of great distress which follows percussion or a fall over the upper abdomen. The immediate

sensation is inability to breathe for a moment, when it is said one has "had the breath knocked out of him." In the more aggravated cases syncope follows with great prostration and nausea.

Taylor sets this type of injury down as an occasional cause of death; for in writing on the subject he says: "There is no medical doubt that a person may die from shock without any external evidence of injury being found after death" ("Medical Jurisprudence," p. 317, 1880). Mr. Hodgen is emphatic in his statement that death may immediately follow an injury of the abdomen without any external or internal evidence of it being discovered on autopsy.

"There may be," he says, "a slight abrasion or contusion mark on the skin, but these are neither constant nor necessary accompaniments of the blow. Convictions of manslaughter have taken place under these circumstances" ("Abdominal Injuries," Holmes' "System of Surgery," vol. iii, p. 217). Mr. Alfred Poland (*ibidem*), in his prize essay on the subject, said that "the upper part of the umbilical and epigastric regions contains such vital structures, and above all, the solar plexus and its numerous branches, of such high organic importance, covered in by soft parieties, but little capable of receiving or transmitting external shock, that it is not to be wondered at that death may be the immediate consequence of injury in this region." We are told that in the March circuit at Cambridge, England (1857), John Bond was indicted for the murder of his wife. He beat her violently over the stomach with a six-pound codfish. She died almost at once after the first few blows were delivered (Holmes' "Surgery," vol. i, p. 885).

Austin Flint (2d) records a case of death resulting from a blow over the epigastrium. The patient was a young man who had been hit playfully by a fellow-waiter. Flint made the post mortem examination and declared that he could find nothing to account for death ("Human Physiology," revised ed., p. 912). Chavasse in 149 observations on deaths from abdominal injuries reports 36 of them as having been induced by kicks from horses and 13 by kicks from men. Guthrie records the case of a male infant which was projected up in the air about six feet, his father catching him as he came down over the abdomen, his thumb projecting upward. The infant died almost instantly. On autopsy an extensive rupture of the intestine was found (Guthrie, "Principles of Surgery," p. 217).

PERCUSSIVE VIOLENCE OVER THE EPIGASTRIUM AS A CAUSE OF DEATH.

Can a blow on the stomach or anterior abdomen produce death without producing such pathological changes as can be traced or detected afterward?

In this materialistic age of ours, when it is assumed that symptoms are always but the expression of organic changes and when facilities are at our command for purposes of rigorous analysis, it might seem that a prompt and definite answer could be given to this question. Still, truth demands that, however humiliating it may seem, it must be confessed that there is a multiplicity of morbid manifestations which have no tangible, visible organic mutations that will account for them. Their fountain head is the nervous system and vital changes. Possibly those rare cases of sudden death after a blow on the abdomen belong to this category. The anatomical, physiological and vital relations between the stomach, heart and brain are most conspicuous, and these are always most clearly accentuated in what we designate functional maladies. In my search through the authors for evidence to support or refute the assertion that death may follow a blow on the epigastrium, the results were unsatisfactory, for there was great discord of opinion, and in some works by eminent surgeons which were examined this class of injuries was scarcely mentioned.

The general tenor was in the direction of skepticism, and anything approaching a positive opinion could be found in but rare instances.

I could find no author who had ever had a well-authenticated case in his own practice, though there was no paucity of hearsay evidence and ingenious theorizing.

Ashurst says that "since Pollock's researches, it appears doubtful if rapid death can follow abdominal injury; though there can be no question but rapid death may follow those injuries, either from concomitant shock or from a condition of the solar plexus analogous to cerebral concussion; in either case, however, there

would probably be physical lesions after death" (Ashurst's "System of Surgery," p. 391). This statement is so ambiguous as to carry no positive force, for every one knows that certain abdominal injuries are quickly mortal; but they have a definite pathology. The physiological comparison between the solar plexus and the brain will not hold.

Mr. Thomas Bryant ("Treatise on Surgery," p. 278) is scarcely less equivocal on this point. He says that "under certain circumstances a trifling blow on the abdomen may give rise to symptoms of an alarming nature . . . the absence of shock may lull suspicions;" and he adds, "however trivial an injury of this kind may seem, it should be regarded with apprehension and the utmost caution and care manifested in its treatment. How far sudden death is attributable to shock or collapse from a blow on the abdomen without organic lesion is an open question."

Le Gros Clark ("Surgical Diagnosis," p. 207) maintains that shock in itself is not a reliable criterion of how extensive a deep lesion may be, and warns us not to be too precipitate in making a favorable prognosis.

Agnew was reserved on this question.

Dr. Sanborn's case, which occurred in Lowell, Mass., is interesting in this connection. The patient was crushed against the side of a house by the handle of his hand-cart hitting him on the stomach. He felt faint for a moment, but pushed his cart into the shed.

Violent symptoms followed, and he died in forty-eight hours, when a large rent was found in the small intestine (Boston *Medical Journal*, May 12, 1859).

Pirrie believed that blows received over the stomach or duodenum were more dangerous than those in other situations ("Principles and Practice of Surgery," p. 598).

Miller observed that a contusion of the abdomen, though it might leave no visible marks on the integument, yet might do great internal damage; and further, when the deep viscera escaped, the chances were that in consequence of the damage to the abdominal muscles atrophic changes and weakening were quite certain to follow ("Practice of Surgery," p. 216). Le Gros Clark adds that "if the doctrine be true that a blow on the abdomen may cause death, it must be a very rare accident." Holmes practically repudiates the doctrine *in toto* ("Encyc. Surg.," vol. ii, p. 854).

Hunter McGuire, of Virginia, has reported a case of a soldier who was killed by a spent ball hitting him on the belt over the abdomen. On autopsy nothing was found to account for death.

Guthrie believed that violent blows over the anterior abdomen might lead to its ultimate absorption and relaxation, thereby favoring the advent of hernia without rupture of muscle fiber. He cited such cases in his own practice.

Gaut adds his testimony to the probability of blows over the abdomen causing fatal results, and says that "wasting and weakening of the abdominal walls is one of the consequences of severe percussion here" ("Science and Principles of Surgery," vol. i, p. 532).

With a view of determining as far as possible the views of surgeons on the question of contusions of the abdomen in recent times, since surgery of this region has so largely occupied the attention of the profession and operations have been performed on a prodigious scale, an examination was made of nearly all the leading contemporaneous exchanges, domestic and foreign, that have been issued during the past fifteen years.

The most conspicuous feature in the search was the singular paucity of cases chronicled. It may be said that during this period the subject of abdominal contusions has not received the attention which its importance merits.

During that space of time there was no case recorded of death from abdominal contusion of that character which is devoid of pathological lesion.

It may be said that in recent times the general tendency of the profession is to deny the possibility of death from an abdominal contusion, without tangible evidence of disorganization of structure succeeding.

Modern studies, research, experimentation and personal observation all tend to discount and repudiate the assumption that death is possible by a blow anywhere over the abdomen of a man in sound health, without gross structural lesion succeeding.

Mortal concussion of the brain at the present is denied by many of our ablest authors. And concussion of the spine

without serious central changes has been incontestably and conclusively proven to be little more than a mere myth. Probably concussion of the abdomen rested on an equally shaky foundation and has had practically nothing to support and perpetuate it other than the parrot-like practice of the past in copying from one work into another notions which were wanting the stamp of personal observation and had nothing to support them except their hoary antiquity.

CONTUSIVE AND COMPRESSIVE INJURIES OVER THE ANTERIOR WALLS OF THE ABDOMEN, INVOLVING THE DEEPER ORGANS.

Although since 1882 but comparatively few cases of the description here considered have found their way into current medical literature, yet they constitute a considerable share of all traumatisms in every hospital.

They are not, however, by any means as common as injuries of the head or thorax, though an equal or greater surface is exposed. This is because, as heretofore explained, the abdomen is best protected, and owing to its physical composition it is best capable of resisting injury.

The consequences attending or following an abdominal bruise will always depend on various circumstances.

First, the region which has sustained impact.

Secondly, the volume of force and its quality.

Thirdly, the structures involved.

We have but a vague conception of the extent of abdominal resistance and of propulsive power until we have an opportunity to observe it in the parturient act or when we have opened the abdomen in the living man and observed the tremendous energy sometimes required to hold the intestines back when violent retching sets in and all the abdominal muscles are brought into play.

Local abdominal bruises are often witnessed. Blood may be extravasated into the muscle's sheath and cellular tissues, nerves lacerated and tendons strained.

In this class recovery is rapid and full function quickly restored. Parietal lesions of a more serious character may, however, follow later on.

Rupture of the muscle may succeed. In one case, cited by Camper, the rectus was lacerated and the internal epigastric artery opened, the patient sinking in six hours from internal hemorrhage (Camper, "Contusions de l'Abd. Au. Ch.," vol. viii, p. 712).

LOCATION OF INJURY.

Inasmuch as the abdomen is not equally protected, its contents varying in mechanical resistance, in their vulnerable qualities and in their exposed position, it follows that the effects from the same volume of force must vary according to its point of impact. Thus when a blow is delivered over the scrobiculus cordis, over the great centers of the sympathetic or the pneumogastric and in close contact with the cardiac organs, we may expect greater shock and functional disturbances than if the same volume of force was delivered over the loin or elsewhere.

A blow directed obliquely would be capable of less disastrous consequences than one aimed directly over the median axis of the abdomen in the direction of the vertebral columns.

Violence applied over the walls of the thoracic vault of the abdomen, when not too great, is reflected back by the elastic lung and ribs.

It is probable that pure concussive force, however applied to the abdomen, is often so diffused as to impinge equally on all the floating viscera.

But with the *direct compressive* quality, as will be seen, the damage is sustained at a point in close vicinity to where violence has been inflicted.

Indeed, there is no proof that there ever are disorganizations of the viscera by *contre coup* force in abdominal injuries as we often witness them within the skull.

VOLUME OF FORCE AND ITS QUALITY.

It is clearly evident that in all abdominal as other injuries, much depends not only on the volume of force, but the manner in which it is applied.

Percussive force, as kicks or blows, derive their destructive quality from their velocity, concentration of action and the limited area of their impact.

Hitting a hollow viscus which is distended with gas or liquid, as the small intestine, the bladder or stomach, may cause a rupture of it.

This same quality of force when brought to bear on a solid organ shivers or lacer-

ates it, reducing what it strikes, perchance, to a pulp.

Compressive force is slower in action and probably attended with less danger to life than the former. Owing to this characteristic, movable organs are permitted to shift into such situations as will afford them most protection, besides adapting themselves to best resist danger.

This perhaps may explain why the distended stomach and intestine so often escape after great weights have passed over the abdomen.

But the effect of a crush, as in a buffer accident or under other circumstances, is widespread and produces a lesion which involves a whole organ and contiguous structures.

Thus in a man crushed by a loaded cart-wheel, under my care a year ago, there was coincident laceration of muscle, omental hemorrhage, rupture of the ilium and contusion of the right kidney. The shock following compressive injuries is sometimes very great, though in my experience it is not so dangerous as that seen in contusive variety.

IMPORTANCE OF STRUCTURES INVOLVED.

If we proceed from above downward, we will observe that the spleen and stomach are so situated as to best escape force, the latter particularly when collapsed and contracted.

The liver, too, is well sheltered. The gall-bladder is more exposed and hence is more often damaged. But when great force is applied over the floating ribs on the right side the liver is crowded against the spine and lacerated. Rupture of this organ is serious because of its great vascularity and the danger of mortal hemorrhage following. The same may be said of the spleen.

In the umbilical region the ilium lies close to the abdominal walls and is in great danger in event of injury. Certainly all will depend on whether more than one or two of its coats have given way, and whether the rent is a small or large one; possibly also on whether its leakage consists of gaseous or liquid elements.

The vertical segments of the colon are so well protected that they seldom rupture. When they do their fecal contents excite prompt, septic inflammation.

The kidney is frequently injured. When the trunk is seriously contused, or compressed over the lumbar spine, and when great force is applied over the loin anteriorly, it may also suffer contusion. If, however, it is peculiarly vulnerable, it likewise possesses marvelous recuperative power; but when its large blood-vessels are opened death may follow by rapid exsanguination, the blood draining off either by way of the bladder or infiltrating into the connective tissue.

The organs of the pelvis are safe from harm unless their osseous shell is crushed in or they are distended and rise in the abdomen, as do the impregnated uterus or the enlarged bladder. Rupture of the bladder when the tear is completely through all its coats and intra-peritoneal is a serious accident, though it is a rare one which but few ever witness. The ureters, chyle ducts, pancreatic duct or the thoracic duct are sometimes ruptured, when the more superficial organs entirely escape.

A case of rupture of the common bile duct has come under my care which was caused by the patient being run over. The case ended fatally on the sixth day, and on autopsy a rupture of the common duct was found, though all the other neighboring organs were sound.

A case of rupture of the thoracic duct came into my service last year, caused by a run-over accident, the patient recovering.

Traumatic rupture of the ureter has been reported.

The vascular system is nearly always implicated in serious abdominal injuries, and the presence of a large hemorrhage in many is a contributory cause of death.

IS THE ACCEPTED CLINICAL PICTURE OF GASTRIC ULCER CORRECT?*

A. L. BENEDICT,† A.M., M.D., BUFFALO, N. Y.

The ordinary conception of gastric ulcer is that it occurs by preference in females, especially in anæmic young women under twenty-five or thirty, and that it is attended by superacidity.

From Ribbert's series of 3,476 autopsies in Zurich and Nolte's series of 3,500 in Munich I have computed the following table, showing the average proportion of gastric ulcer in 10,000 miscellaneous corpses, equally divided between the two sexes. As so few cases occurred in childhood, I have appended a column, computed from actuaries' statistics, showing the number of deaths in each decade, starting with 10,000 persons at the age of ten. The same proportions ought to hold good for the ages of a miscellaneous collection of 10,000 corpses as if we followed any particular group of 10,000 to the time of their death.

Stoll shows that the greatest mortality from gastric ulcer (or at least the greatest number of ulcers found post mortem) occurs in the fifth decade of life, and nearly as many in the third, sixth and seventh decades. Considering, however, that more and more people die in succeeding decades up to the ninth (see fifth column of table), a slight modification of Stoll's deductions is necessary. The last column of the table shows that the liability to death with, if not from, gastric ulcer reaches its maximum about the age of forty and diminishes almost equally as we ascend or descend from that number.

CASES OF ULCERS.

Age.	Male.	Female.	Total.	Probable No. of Corpses.	Percentage of Cases of Gastric Ulcer in Each Decade.
Fœtal	1	0	1	0	0.0
10–20	2+	7	9	600	1.6
20–30	7+	10+	18	700	2.6
30–40	12+	21	33	800	4.1
40–50	18+	18—	36	900	4.0
50–60	12+	19	32	1,300	2.5
60–70	4—	24+	28	1,900	1.5
70–80	5	15+	20	2,300	0.9
80–90	1+	0	1	1,300	0.08

As regards sex, Ribbert found 2.59 per cent. to be the liability for females; 1.83 per cent. for males. Nolte's proportions were 1.23 per cent. and 0.8 per cent. respectively. It will be noted that from the tenth to the fortieth year males are more prone to violent deaths than females and, conversely, are less liable to disease. In the fifth decade, when the two sexes lead similar lives the relative frequency of ulcer is practically equal. The preponderance of ulcer in old women is, I believe, partly due to the fact that after middle life there are more women living and, paradoxically, more dying than

* The writer disclaims all originality of research in this article, which is based on one of Dr. August Stoll, of Zurich, published in the *German Archives for Clinical Medicine*, October 26, 1894. Dr. Stoll, in turn, acknowledges his indebtedness to a number of authors to whom due credit is given as they are here quoted. The extreme length of Dr. Stoll's article—which would fill an entire number of THE REPORTER except the pages devoted to miscellany—prevents its appearance as a translation.—A. L. B.

† Lecturer on Digestive Diseases, Dental Department University of Buffalo.

men. Thus gastric ulcer is not preëminently a disease of youth and the female sex, but of the middle-aged of either sex.

In comparison with the statistics of autopsies, the following series of Eichhorst at Zurich is of interest. His 90 cases were diagnosed clinically, all but 18 recovering. Of 7,720 male patients, 55 had gastric ulcer; of 4,625 females, 35 had ulcer; 71 per cent. and 73 per cent. respectively. I have added to this table a column showing approximately the percentages of a miscellaneous population between the tenth and seventieth years as they would fall into decades. It is by no means certain that a similar division of hospital patients would show the same not been altered to show proportions in 10,000 cases. Considering that almost equal proportions of male and female patients had gastric ulcer, it was not thought necessary to adjust the table to a scale of 10,000.

Stoll concludes that latent cases of ulcer are rare. Of the 90 patients, 25 were not incapacitated till the time of pronounced hemorrhage, but all had suffered from some form of gastric disturbance.

It is difficult to depict any clinical type. Stoll found constipation in 32 cases; coated tongue in 25; diminished appetite in 21; albuminuria in 5; indicanuria in 16; very good appetite in 8; diarrhœa in 6; family history of stomach trouble in 12. Not one of these observations is of

EICHHORST'S SERIES.

Age.	Number of Cases.			Percentage of Whole No. of Cases of Gastric Ulcer by Decades.	Percentage of Population by Decades, excluding all under 10 and over 70.
	Male.	Female.	Total.		
10–15	0	0	0	3.3	21
15–20	2	1	3		
20–25	3	6	9	32.2	19
25–30	13	7	20		
30–35	8	8	16	30.0	18
35–40	7	4	11		
40–45	6	2	8	21.1	17
45–50	8	3	11		
50–55	4	1	5	10.0	14
55–60	3	1	4		
60–65	1	1	2	3.3	11
65–70	0	1	1		

percentages, so that the comparison is a very crude one. While the second and seventh decades furnish the same proportion of cases of gastric ulcer, it must be borne in mind that there are just about twice as many people living in the former as in the latter decade. It will be noticed that while the autopsy reports showed gastric ulcer to center at the age of forty, these statistics move the maximum point ten years earlier. However, the average age of the fatal cases was forty-three years, the youngest being thirty.

Unlike the previous table, this one has any assistance, either positively or negatively, in the diagnosis of a doubtful case.

Thirty of the 90 cases were examined as to hydrochloric acidity, the examination being only qualitative except in 4 cases and made sometimes after a test-meal, sometimes on vomited matter without noting the time after eating, sometimes on wash-water after lavage. In 5 cases there was non-acidity after a test-meal, one of these cases being a carcinomatous ulcer. In two or three cases (one in which quantitative methods were used and one or two

in which the stomach contents after dilution still showed the phloroglucin-vanillin test) superacidity is clearly made out. The remainder are normal as to acidity, or else the tests were so made as to have no definite value. There are not more than 11 cases in which superacidity is even hinted at. Seven quantitative tests were made in 4 cases, the hydrochloric acidity varying from 1.05 to 3.3 in 1,000, the normal ratio being about 2 in 1,000. Kugel's 18 cases of peptic ulcer showed normal acidity in 8, superacidity in 4, sub and non acidity in 3 each. The most liberal interpretation of these two series, comprising almost 50 cases, would indicate that superacidity, to which so much value is attached in the diagnosis of gastric ulcer, occurs in not more than 20 per cent. of all cases, while the acidity is below par in about 25 per cent.

Absorption, as determined by the administration of potassium iodide in capsule, was shown to be normal in 6 of 28 patients, iodine being found in the saliva after seven to fifteen minutes. In 6 others absorption was delayed to twenty to twenty-five minutes, and in one to forty-five minutes. Personally I am inclined to doubt the reliabilty of this test, especially unless the solubility of the capsules is proved by control tests.

The location of gastric ulcer is at or near the pylorus in 60 per cent. of male cases; on the lesser curvature in 40 per cent. of female cases. Otherwise there is no predilection. Stoll explains the sexual difference as follows: In men the weight of the liver, descending with costo-abdominal respiration, forces the gastric contents repeatedly against the pylorus. In women the lateral constriction of corsets changes the shape of the liver and makes the right side of the stomach—that is, the lesser curvature—bear the brunt of the respiratory impact. Still, not all of the female cases were those of corset-wearers.

In 15 out of 75 cases and in 11 out of 18 death resulted from perforation. In 4 of the former series (seen at autopsy) an open artery was found at the bottom of the ulcer, and in several of the 18 cases death resulted directly from hemorrhage. Other complications are not particularly significant.

One patient, a woman aged forty-seven years, who was in the hospital at Zurich for six months without much change in her condition, eliminated a great deal of urea by vomiting. There was no other indication of renal disease. For example, May 21st the urine amounted to 200 c.c., containing 1.4 gm. of urea; the vomited matter, 1,600 c.c., contained 12.8 gm. of urea. In about 25 examinations the total daily elimination of urea ranged from 2.4 to 15.6 gm., fully half of which was eliminated by the stomach. Considering the emaciation and quietude of the patient, 0.20 gm. would be a normal elimination. It is not definitely stated whether the vomited matter was mainly blood or not, except in one or two instances, when the gastric elimination was slight and when the vomit was only tinged with blood. I have several times noticed that the stomach eliminated urea in renal insufficiency, but in cases of gastric catarrh, not ulcer. The catarrh in these cases was due to circulatory changes, especially chronic congestion.

I believe we may conclude—

1. That gastric ulcer occurs slightly more often in women than in men, but not directly because of their sex.

2. That three-quarters of all cases occur between the ages of twenty-five and sixty, the maximum of occurrence being at the age of thirty, of death at forty. That the occurrence of gastric ulcer, either fatal or not, falls off rapidly as we investigate younger persons, slowly as we consider older ones. That many ulcers that are found post mortem have occasioned no clinical symptoms.

3. That superacidity, while doubtless predisposing to the formation of an ulcer, seldom persists after its establishment.

4. That aside from hemorrhage, pain and tenderness are almost the only diagnostic symptoms that are to any degree reliable.

5. That death from ulcer occurs in a plurality of cases from perforation and peritonitis; seldom directly on account of hemorrhage; in the majority of cases from exhaustion and various intercurrent or complicating affections.

"Our preacher made a big mistake last Sunday and lost a collection," said a Manchester man. "How?" "Well, he appointed a tax collector to go around with a plate and every man in the congregation asked him to call again."—*Tit Bits.*

THE HUMBUGGERY OF THE HUMBUGGED.

S. S. TOWLER, M.D., MARIENVILLE, PA.

While it is to be admitted that there is still a large field for cultivation in the line of "psycho-therapeutics," and also conceded that there is more than "something" in it, it must be full as readily admitted that the profession is as apt to slop over in the effort and offer and swallow as sense as fair a lot of trash in that line as it has done in the past in some other studies. Advanced as we are in this ninety-fourth year of the nineteenth century, it takes some time to separate the wheat from the chaff, and we have frequent cause for a little blush when we discover how credulous we have been. We admit of many cures through "mental therapeutics" by all sorts of methods and perhaps take but little thought of whether we have not been largely fooled ourselves in the contemplation of the process.

It is an old, old story—that of pilgrims visiting shrines and leaving, as they did at the chapel of Father Mollinger in Pittsburg, "crutches by the cord." The story and romancing of quackery is just as old, while Christian science and faith cure have long held, under some name, a hold on many minds. Some writers in the regular profession only see in it a rational process that can be comprehended by the profession, but not explained to the lay mind, while others look upon it as a process not yet understood and one that the profession should seek to understand and utilize. So the proposition has arisen that the way to combat the "Christian scientist" is to do the same works and explain the process as best we can by study and research.

In this view of the question, let us first remember that just the same cures which the quack and all his allies claim to have done have been done by educated physicians time and again. True they did not claim to do them by "mental cure," hypnotism nor any other mysterious process. They loudly proclaimed by all sorts of advertisements that it was all done *secundum artem*. They asserted (or rather do assert, for there are hundreds of them still in the business) that they were so superior to all other medical men in skill, so far advanced in medical knowledge, that they could do what no other medical men ever did. So far as the general public ever knew, they accomplished that very thing. Their triumphs were just as great, their cures just as good, their clientage just as large, and their fees larger than any of the first classes mentioned. True their course was not and is not considered reputable by ethical practitioners, but the fact remains that they were and are educated physicians and did do and are doing, without any claim to the mysterious, all that the quack, the Christian scientist or any other of the same class do.

It is not an uncommon thing to see a crowd numbering hundreds pressing their way into a hotel to visit a traveling doctor whose diploma was issued by time-honored Jefferson or by Pennsylvania's great university. The lame and the halt, the blind and the deaf, the old, old chronic—all sorts and conditions of patients are there. The "cords of crutches" are left, the deaf hear, the lame walk, and nine out of ten declare themselves better. How many were permanently better is never known; how many fooled themselves and perhaps fooled the doctor is never found out. But we do know that it is the same old scene over and over again, and that on the arrival of the next "great wonder," regardless of name, a great majority of the faces and forms of the afflicted throng are very familiar; they have been, like the "wonder," in the same business many times before.

We pass all this by with a feeling of contempt for both doctor and patients; we say he humbugged them; we see nothing mysterious in the process; and yet when a Christian scientist or quack only imitates the "regular," we are alarmed at the exercise of a power that cannot be explained. There is certainly nothing more wonderful in the one process than in the other, and success, such as it is, largely owing to the same causes. Under a vast proportion of it all from beginning to end is to be found delusion.

Take a common case in every-day practice. A female patient wakes up some morning with "that tired feeling," perhaps a trifle anxious as to the time of

month it is. She takes down the "patent" almanac, and in hunting up a date she begins to read. In half an hour she has found herself possessed of half of the diseases mentioned in that wonderful "manual of health." Before night she is "quite ill" and next morning is taking the first of "six bottles to be taken before cured." She finds in that almanac wonderful cures of as many diseases as sinners ever suffered or that fled at the sight of the bones of a saint. Some new thing, some change in family affairs or environment, happens, and she is "cured,"(?) and that medicine of course did it. This is related to all her friends, and a host of them "feel the same way" and go through the same process. Those who are disappointed in results fly to some new cure, the quack, Christian scientist or the traveling doctor.

Say she goes back to the family physician, and then comes the rub for him. If he tells her the truth, ten chances to one he loses the patient. If he humbugs her and leaves her to her delusion, accepting her diagnosis and treating her on the strength of that delusion, he adds laurels to the crown of the quack. For be it everlastingly remembered that we cannot assert and claim to do what we do not do without opening the door to the worst imposture.

Indeed, it is at least doubtful if quacks and Christian scientists, etc., could have had the glory to which they have attained if educated physicians had been more honest. If we will magnify simple complaints into serious diseases for the sake of making ourselves famous and our pocketbooks fatter, we cannot complain if the quack claims to cure these same misnamed serious disorders. If we humbug the patient, the patient will humbug many others; these in turn continue the process. They don't all go to the original humbugger, but go with his diagnosis to the quack. Some of them get so deluded that the original humbugger fails to cure them himself, by mental therapeutics or otherwise.

To the young man entering an already overcrowded profession the temptation is great to assume a great deal. He has read of the "called-out-of-church" expedient, of the "horse-rushed-out-of-town" dodge, of "tricks of the trade" almost unnumbered, until he feels, in truth, that

> The whole world loves the modest man,
> Whether he be great or small,
> But yields up its plunks in great big chunks
> To the man with a surplus of gall.
>
> The whole world loves the quiet man
> Who's as silent all day as the owls,
> But needless to mention it gives its attention
> To the fellow who gets up and howls.
>
> The whole world loves the peaceful man
> Who sees no occasion to bicker,
> But the full right of way, you'll permit me to say,
> It gives to the strenuous kicker.

"Gall wins," he says to himself, and then farewell to all that was in him of the true physician and all hail to anything, everything that brings notoriety if not fame. He struts down street; he rushes to the drug store with an empty bottle; he slams in and out of the office; every case is extraordinary; the treatment a new departure and every recovery "a snatch from the brink of the grave."

This class of doctors is quite numerous. Some of us smile half in amusement, half in contempt, at the performance, but how few think of how very, very much it all adds to the triumphs of the quack and the disciples of "Mother Eddy."

Again, we grow sarcastic in disgust at the humbugged laity, and seldom care to acknowledge that we have been humbugged ourselves. We say, "They read the advertisement and believed it;" "They swallowed the patent-medicine almanac and got sick." But what about that time that we received a circular setting forth the particular virtues of, say, "Hoang-nan comp.?" We are given a few pointers from a materia medica, the information that "it can only be got in its simple purity and according to scientific formula from Rubs & Dubbs," and that it is just the thing "for those hardly definable cases that so often puzzle the busy practitioner." Then follow certificates (more or less like those in the laity almanac) from various medical men and a few professors and a quotation from a medical journal. We don't stop to read up on "Hoang-nan" or to take into consideration what the "comp." stands for, nor if there may not be something incompatible connected with its use; but we try it on one or two cases "to see how it works." If the patient gets better, then our name too is added to the list of "eminent physicians who commend this remedy." It was the professional bait that was swallowed—that was all the difference between

us and the laity, save that the latter were more excusable. It is all of a piece with the delusions of the deluded who go in crowds to the quacks, the Christian scientists and the educated traveling and largely advertised doctor.

Beneath the humbuggery and delusion lies this: Where an objective mental condition becomes a subjective mental condition, all things are possible to it viewed in the light of its own reflection or that of a stronger mental condition. The great majority of persons cannot be said to really think; many think they think, the few truly think. These last are the only investigators. Again, we are all more or less like sponges—we absorb the element into which we are thrown, and that unconsciously to ourselves. The orator sways his audience at his will, especially if they have gone prepared to be swayed. The quack and the Christian scientist command and succeed with the neurotic case because the patient has placed them in command from the start. The patient goes in the subjective condition. The traveling doctor occupies the same advantage and cures the neurotic case, for at least the time, when you had failed. Put it right down in your mental diary that the most probable cause of your failure was that the patient knew you too well. In spite of all you had done in the family for years, in spite of your successes, you were after all to her a very familiar personage and had become common. All the psycho-therapeutics you can invoke won't do you a bit of good; her mental condition, so far as you were concerned, was not subjective. But go off a hundred miles, fill your office with patients, let that same old client pass through the throng to your consulting-room, and dollars to doughnuts you cure her in great shape.

To a great extent we are all "just so." In certain subjective conditions we receive, we believe, we are controlled. The woman reads the almanac in that frame of mind, the doctor in the same mental shape becomes subjective to the circular. The student swallows all that the professor says, no matter whether it be the vagaries of Samuel Hahnemann, or a revival of the tractors of Elisha Perkins, or the sound common sense of honest Horatio C. Wood. Speaking of Hahnemann and Perkins, it is a valuable piece of history to remember that Hahnemann was opposed violently and even savagely while Perkins' tractors were received with favor by quite a number of the learned regular profession. In London thousands of cures were published and certificates from professors, physicians and surgeons and clergymen added thereto. In Denmark volumes of cures were published by authority of physicians of high standing, yet Hahnemann was a scholar, while Perkins simply humbugged with two pieces of metal. To connect the two periods of then and now we have only to remember that the works of Hahnemann are still used as "text-books" and the theory taught in certain medical schools, while the practice has been largely abandoned by the professed practitioners. Also to remember that the long catalogues of complicated machinery that are advertised (and readily sold) under the head of appliances, splints and instruments exhibit a tendency to slop over in that line in a degree equal to the patrons of Perkins' tractors. Dr. Joseph Eastman's story illustrates this. He says: "The professor appeared before the audience and waved a new medical instrument before them for five minutes and then said: 'Gentlemen, the only reason I have for this exhibition is to say that this instrument cost me eighty dollars and isn't worth a damn.'"

A reader of a pet medical journal gulps down without a struggle all that his patron saint writes, and the doctor who "thinks he thinks" becomes the most conceited man of the lot. Haven't you read an article in that subjective mood, gone out and followed it to a dot, and about a week after, when you were in the objective case, wanted to kick yourself all over your own bailiwick for doing it? I have, and I must be a far more singular person than I take myself to be if many readers of this article have not felt just so.

Again, we grow indignant at the lay advertisements of "Pennyroyal pills" and "cotton-root" mixtures for the prevention of pregnancy, and yet never kicked (except in our mind) when medical journals advertised pessaries and fixtures that had no other purpose and whose use could only produce an abnormal condition of the uterus.

There is little room to expect improvement of the laity in the line of humbuggery until we have advanced beyond it ourselves. I am not in controversy with any of the known or unknown quantities

of psycho-therapeutics, but I do assert that nothing has been done by the "Christian scientist" or any other of his kith or kin but what has been done again and again by educated physicians, and can be done by any one who is willing to adopt the methods. Those methods, however, involve a great deal of deception and the humbugging of the humbugged. I further assert that no reliable proof has been offered that these people ever cured by mental therapeutics a case of a veritably diseased organ or a neurotic case originating in and from a diseased organ.

It is a matter of common knowledge that the average doctor pays either too little or too much attention to his neurotic cases. If able to pay, the tendency is to slop over and become too fussy; if poor, they become a source of annoyance to many, but little attention is paid to them, and they become the prey of the quack. Again, there is that quite numerous class who will not make any effort to pay the local physician (and of course he does not want to spend his time for nothing on cases of that kind), yet always manage to raise a five or ten dollar fee for the traveling M. D., the C. S. and the quack.

But it is a mistake to think that mental cure, or influence of mind over body, is not very largly recognized by the profession. It was so taught even in ancient days, the "placebo" is an old-timer, and bread pills have cured(!) many a patient in years long gone by. It was and is only one of the ways of administering "mental cure." To-day all forms of nerve disorders as well as imaginary troubles are claiming more thought and research than ever before, but the methods have nothing in common with the ignorant quack or the—perhaps—self deceived Christian scientist.

The painful reflection is this, that there are eight thousand physicians in this State alone, and if they were actuated by a common purpose, common honesty and with a common proficiency, what a power against all forms of quackery and medical fraud they could and would be! That they are not so is largely responsible for the success of the frauds; and that they are not so is very fair evidence to the laity that there is something wrong in our general make-up. The remedies for what have justly been called "these abuses" on the part of quacks and all their allies are: first, professional honesty; the setting of our faces like flint against deception of any kind in and out of the profession; a common purpose to raise the moral standard as high as the great responsibility of our calling demands; a common purpose to elevate and help each the other "in the spirit of unity and the bond of peace." Second, a remedy helpful to the end wished for is in (as has been already suggested in Dr. Langsdorf's paper on "Christian Science") appropriate legislation. There are no good reasons for permitting sacrifice of human life by faith curists, any more than by any other class of ignorant practitioners. Third, by the education of the public.

The first can only be accomplished by bringing all fair practitioners into the local, State and national medical societies. The second can only be accomplished by exhibiting to the Legislature unquestionable proofs and instances of life sacrificed through the ignorance of the parties using the method denounced. The last can best be accomplished through leaflets for common distribution and the use of the secular press. To reach people we must use the channels that pass into and through their homes. The State Board of Health has done untold good by the liberal distributions of its circulars and leaflets on sanitation—disinfection, diphtheria, scarlatina, typhoid fever, etc. And the good has been greatly aided, the advice given more generally received, because it bore the impress of the Commonwealth. In short, it came with authority. The power and dignity of Authority with a big A is a great educator. Leaflets should be issued by the Board of Health and also by the State Society, thus carrying with each utterance the authority that commands respect. The secular press should be used by a series of articles from men whose very names demand attention and whose "copy" the press will be glad to get. Above all, let every lesson be taught in plain language for plain people. "University extension" is a laudable enterprise; let us extend its principles to the line of preventive medicine and the uprooting of humbug.

HOAX—I hear Judson is making over $1,000 a day. JOAX—Get out. HOAX—Yes, he is; he's a coiner in the mint.

CHOREA.

W. B. ATKINSON,* M.D., PHILADELPHIA.

Chorea, or St. Vitus' dance, by which name it is so well known among the people, occasionally proves so intractable that fears of grave results are felt. Thus the convulsive movement may become so pronounced as to totally prevent sleep until the child is utterly exhausted.

Recently I have had several cases come under my notice, in each of which sleep was so broken and unsatisfactory that the parents feared for the life of their child. One, a girl aged thirteen years, from the ordinary stature of a girl of that age had suddenly shot up into a tall, thin figure, rapidly losing her power of study, becoming greatly emaciated; in short, showing every symptom as if the waste would speedily cause death. Owing to my absence from the city she had been under the care of another practitioner, and so far as could be learned, every proper means had been employed in the hope of toning her system and restoring her nerve power. But after the lapse of several weeks, upon my return she was brought to me in a pitiful condition. While she appeared to have partially regained her appetite, not the slightest result had been obtained in the control of the convulsive movement. She was so constantly jerked in every muscle that she was unable to stand or walk without support. In eating great care was needed to prevent biting the tongue and choking. From this condition and her sleeplessness due to the convulsive motions it became imperatively necessary to procure rest at once. My prescription was:

Chloral	ʒij
Ext. cimicifugae fld	fl ʒij
Elixir simplicis	fl ʒiij

Sig.: One dram every three hours.

She was directed to take the first two or three doses at intervals of one, then two hours, in the hope of procuring sleep. She did not present herself again for some four weeks, and then every symptom of chorea had disappeared. She was gaining in flesh and in every way was markedly improved. I was informed that after several doses on the first day and night sleep was obtained. Next day she showed the advantage resulting from this refreshing sleep in renewed appetite, almost entire disappearance of the movements; in short, from that time her progress to health was rapid.

In the treatment of a large number of cases of this affection, while I have met with a number which were rather stubborn in yielding, this was the worst, but at the same time the one which yielded most readily to the positive treatment instituted. My usual plan is to ascertain the cause and remove it if possible; then build up, which is generally needed, and employ the cimicifuga in positive doses. The chloral is added only when the movements continue in spite of treatment.

A similar case occurred in my practice many years ago and before I had learned the use of chloral. In this, it being a sequel of rheumatism, the child became so much exhausted from loss of sleep, inability to take food, etc., that he appeared in a dying state. Feeling that this would be the result, I administered morphia in rather large doses till sleep was induced. I confess that I watched him anxiously, and was much relieved after several hours to find him awake and really improved.

Cigarette-smoking in a boy of nine years was undoubtedly the cause in a case which was brought to my clinic, and here the cimicifuga combined with syrup of hypophosphites soon relieved the symptoms. Of course the child was carefully watched to prevent his continuance of his foolish habit.

One instance of recurring chorea was due to intestinal trouble induced by the most ridiculous indulgence of the child at the table. He was permitted to eat to excess of any article he fancied. This, although the danger of it was laid before the parents, was repeated again and again, apparently to show the determination of one care-taker to have her own way. Here some form of pepsin rarely failed to aid the other treatment, but occasionally an attack would prove obstinate. The child showed to a surprising degree, after several attacks with their accompanying an-

* Physician to Howard Hospital, Dept. of Children.

noyances, a good sense in agreeing not to indulge in this way, and no more attacks followed.

A great source of difficulty in curing these cases is the tendency on the part of parents to try each new treatment they hear of; to believe the disease to be wholly the result of worms in the alimentary canal, and by the use of quack nostrums, vermifuges and the like, to delay the progress to health and even to make it worse.

Always demand the most earnest attention to your treatment and suggestions; promise a cure if these are carried out, but do not promise a complete cure in too short a time to allow of the tonic and antispasmodic effects of the remedies being fully obtained. When the movements cease continue the remedies in lessened doses for a time, lest a return of the symptoms produce a loss of confidence.

I do not pretend in this brief paper to enumerate the other remedies which often are found of value. Every physician must act as the symptoms indicate and be guided by the results of the remedies.

COMMUNICATIONS.

A CASE OF ATAXIC PARAPLEGIA.*

THEODORE DILLER,† M.D., Pittsburg, Pa.

The symptoms which this man presents are a mingling of those seen in locomotor ataxia and primary spastic paraplegia (lateral sclerosis). The affection corresponds to neither of these diseases alone, for some symptoms are added and others are absent in the clinical picture of each. But on theoretical or *a priori* grounds one would expect to find, when the parts affected in locomotor ataxia (posterior columns of cord) and primary spastic paraplegia (lateral columns) are both diseased, that there would result a symptom complex which would, so to speak, strike an average between the symptomatology of these two affections. Conversely, such an "average" symptom complex would lead us to look for diseased condition in both lateral and posterior columns of the cord. Reasoning on this ground, one would of course expect the "average" of symptoms to vary according as there existed predominance of disease in lateral or posterior columns. As a matter of fact, pathology shows this *a priori* reasoning to be correct. Very often it is difficult to say just what the pathological condition is which causes the symptom complex under consideration. Some of these cases are nothing more than cases of locomotor ataxia in which the morbid process has overleaped the confines of the posterior columns and invaded the lateral columns. In other cases a transverse or diffuse myelitis is the underlying pathological condition present.

These cases of ataxic paraplegia have been frequently described by Westphal, Ormerod, Strumpel, Gowers, Dana, Grasset and others and are now well recognized, at least clinically. They are, however, somewhat uncommon, and I believe that the notes of this case will not be without interest to the Fellows of the Academy.

William C. applied for treatment at the Pittsburg Free Dispensary last January. He is forty-four years old; married; puddler; denies syphilis; uses a great deal of tobacco.

Several weeks before applying for treatment he suffered some pains (not severe) running across the belly and down the thighs and legs to the toes. There was some numbness and tingling of these parts. He has lost much strength in his legs (it is for this that he seeks relief). Knee-jerks are normal or perhaps slightly exaggerated. Distinct locomotor and static ataxia present Gait is perhaps slightly spastic. Pupils unequal, irregular in outline; respond to both light and accommodation, though very sluggishly. There is marked diminution of strength in legs; no loss of strength in arms. No

* Case reported and patient presented at meeting of Pittsburg Academy of Medicine October 29, 1894.

† Physician to Neurological Department of Pittsburg Free Dispensary; Visiting Physician to St. Francis' Hospital.

atrophy. Cincture sensation and slight numbness of legs present. Sexual and vesical functions unimpaired.

Dr. Wishert discovered partial absorption of lens of left eye (accounting for a quivering of iris which is present).

I lost sight of the man during the summer. He returned to the dispensary a couple of weeks ago, his condition very little changed, except that his knee-jerks are not quite so active. He tells me that he suffered some bladder trouble during the summer necessitating catheterization, for which he was treated for several weeks at the Allegheny General Hospital.

The treatment has consisted in large doses of iodide of potash (℥j t.d.) and general faradization. He states he is some better, but he has not been under observation long enough to note results.

The ataxia, cincture sensation, pains in legs with disordered sensation and bladder trouble are suggestive of locomotor ataxia. The preservation of knee-jerks, the very considerable loss of power in the legs and the slightly spastic gait argue against this diagnosis. The girdle sensation and leg pains are not prominent symptoms, and it must be remembered that the patient himself regards the loss of power in his legs as the dominant symptom.

So as we have here a symptom complex representing an "average" between those of locomotor ataxia and primary spastic paraplegia, we may fairly conclude that both the posterior and lateral columns of the cord are involved and that clinically the case is one of ataxic paraplegia.

Whether the case is really an atypical case of locomotor ataxia or whether the symptoms depend upon some form of transverse or diffuse myelitis it would, I think, be difficult to say. I am inclined to favor the first-named view, principally from the fact that atrophy is absent.

So far as treatment is concerned, the diagnostic distinction between locomotor ataxia and ataxic paraplegia is not of very great moment. Yet it has been said that the last-named affection can be more favorably influenced by faradism and electricity than the first named.

TRANSLATIONS.

PULSATING TUMORS OF THE POPLITEAL SPACE.*

TRANSLATED FOR THE MEDICAL AND SURGICAL REPORTER.†

There recently entered the hospital a patient with a tumor of the left popliteal space which presented visible and distinct pulsations. My first impression from the site and the pulsation was that it was a popliteal aneurism, and I should say that all who saw him with me were of that opinion. But when about to exhibit him to you I began to reflect and found myself in doubt. I returned to the patient and examined him again. I then came to the resolute conclusion that it was no popliteal aneurism at all. I shall now present to you the reasons which led me to this diagnosis.

First of all, what are the essential characteristics of an arterial aneurism? The blood, driven forward by the heart-beat, reaches the aneurismal sac; the wave is the result of the pulsation and its distention. Thus there are at the same time an elevation and an expansion of the tumor. In the second place, when the blood penetrates into the sac through a narrow orifice there is in consequence a murmur which in certain situations, as in the popliteal space, for example, may be doubtful or indistinct. Finally, if the aneurism be arterio-venous, and even in the ordinary variety, there is one well-known and characteristic sign, the thrill. Another characteristic, yet one of less importance, is the condition of the pulse below the aneurism, which is slower or less forcible than that of the opposite side.

A true aneurism is either entirely or in part reducible, either by compression applied directly to the aneurismal sac or above or below the sac on the blood-vessel. Now, it is not to be denied that here in this case there are distinct pulsations, but

*A clinical lecture by Prof. Tillaux at the Charité Hospital, Paris.

†Translated from the *Gazzetta degli Ospedali*, No. 96, 1894, by F. H. Pritchard, M.D.

that does not constitute expansion, which is absolutely lacking, and the greatest force of the pulsations, you will observe, is exactly in the middle of the tumor; so if one place his fingers along the margins the pulsation is not noticed. This last feature is a little difficult of comprehension, but it is the expression of the conclusion that there is in this case no expansion, for then it should be palpable in all directions and at all points. And again, we have not succeeded, even with the most careful examination, in discovering the least trace of a souffle, and this was one of the first signs which led me to doubt the diagnosis. The murmur is not present—I can guarantee it—therefore we have an aneurism in which there is neither expansion nor murmur. The pulse in the posterior tibial artery, tried with the finger, seems less strong than that of the opposite side, but the sphygmograph reveals nothing of importance. Therefore this evident diminution of the pulse-beat in force is the only sign of this tumor being an aneurism. I now press upon the tumor and I also invite you to try it, and I find that it is impossible to obtain the slightest decrease in volume, whatever be the position of the limb. On compressing the femoral artery the tumor no longer pulsates, while its original size persists without its decreasing the least. It has a solid feel, but more resistant than that of an aneurism. Place your finger upon the tumor and you will perceive the pulsation; press upon it and it diminishes in force; press still more and the tumor, compressing the blood-vessel, causes the pulsation to disappear. But, you may interpose, an aneurism may be more or less filled with coagula, and from this the tumor is not to be reduced in size and the murmur absent. But the patient has only suffered from pains for six months and for two months has noticed the development of a tumor. The principal sign upon which I base my diagnosis is this: I declare that this is neither an aneurism of the popliteal artery, a tumor attached to the artery, nor an aneurismal sac filled with coagula, and that because if you place your finger upon the growth you will find it absolutely limited and displaceable toward the joint vertically, and that not only when the leg is flexed but also when it is completely extended. The artery remains tense like a cord, and even then the tumor is movable not only vertically but also transversely. It slides upon the artery and is very movable, so that a movement of one or two centimeters may be imparted to it. I do not hesitate to state that we have here a tumor in contact with the artery, but not attached to it.

What is this tumor? Is it a cyst? Several objections might be offered to this hypothesis. Firstly, the tumor is in the middle line, which does not hold true of cysts originating in the tendons and their sheaths. Median cysts communicate with the joint, in which case they would lift the artery instead of, as here, being lifted. I had thought that possibly it might have been a tumor of the sciatic nerve on account of the patient having experienced pain long before he noticed a growth. This was not merely a sense of fatigue nor formication, but an actual pain in the lower portion of the leg on its external aspect as well as in the dorsum of the foot along the musculo-cutaneous branches of the popliteal portion of the sciatic nerve. At the same time you will notice that the calf of his leg on the affected side is about one centimeter larger than that of the sound side. Still, there are numerous objections to accepting this view. The growth is in the midline and outside of the course of this branch of the sciatic nerve, and though Virchow has called attention to tumors implanted laterally upon nerves and even I have allowed myself to be led on by this idea, I dropped it, as the tumor is still movable even when the limb is in extension, when the nervo-vascular fascia of the popliteal space is tense. It is beyond a doubt that it is connected with the popliteal branch of this important nerve, yet only by contiguity, for how could we otherwise explain the painfulness?

Possibly it is an enlarged lymphatic gland. I do not believe it, but I cannot affirm it, for this lymphatic must be in the depths of the space. Of what character is it, then? But such a view is untenable, for patient is vigorous and robust.

I hold that it is a fibrome, and considering its rapid course it may be a fibro-sarcoma; this the histological examination will settle. Still, in the mean time I can state that it is a hard, solid, mobile tumor of neither vascular nor nervous origin, but probably lymphatic.

What is to be done with it? If it were an aneurism I should not try operative measures before having employed others more simple, as compression. But the patient suffers, he is unable to follow his trade, and the growth is in a dangerous location. With care not to injure the external saphenous vein I incise the skin, the cellular tissue and aponeurosis after having applied Esmarch's bandage. I remove the tumor from its surroundings with Museux's forceps and a small spatula.

We have now operated on our patient in the following manner: Having applied Esmarch's bandage, I examined again and felt that the tumor had not changed in volume or consistence, which was another point in favor of its not being an aneurism containing liquid. After having made an incision I found the superficial veins very much overfilled and distended with blood, they being compressed by the elastic fascia. The popliteal branch of the sciatic nerve was seen to cross the tumor; this was liberated and drawn to one side. The growth then came into view and still was found movable. At first it appeared possible to enucleate it, but I at once saw that it was connected with the artery both above and below, so that I decided to extirpate it by Purnamm's method, *i.e.*, after ligation above and below the tumor. No other ligature was necessary. In the depth of the incision you see the popliteal vein distended and greatly swollen. The growth, which is of the size of a pigeon's egg, I now cut through lengthwise, as it is oblong and you will notice that it consists of concentric layers of coagula, to use Broca's expression; no trace, on the contrary, of active clots and all dense, white and fibrinous, while the sac itself is not completely full. We have therefore here a case of spontaneous cure of an aneurism.

I now wish to study with you this case which is so full of interest. I absolutely affirmed at first that it was not an aneurism, though I myself at first sight thought we had an aneurism to deal with, from the totality of the symptoms. Then I told you that it was a tumor in the vicinity of the vessel, but which had not developed at its expense. I therefore have been mistaken. What is the cause of this error? In the first part of my lecture I stated that it was not an aneurism containing liquid, for there is none of the characteristic symptoms, expansion, souffle nor reducibility, and indeed this tumor presented none of these symptoms. But then I remarked, is it possibly not an aneurism full of coagula? I also denied that. If you consult Broca's work you will read the following:

"On sait qu' à l'état de simplicité, l'aneurysme est une tumeur molle, pulsatile, complètement reducible, donnant lieu à une bruit de souffle plus ou moins fort. Ces caractères peuvent être attenués, masqués ou même effacés par la presence de caillots fibrineux. La tumeur peut devenir plus ou moins dure et acquirir même une fermeté comparable à celle d'une tumeur fibrineuse. On ne sent qu'un soulevement obscur, et si la tumeur est placé sur le trajet d'une artère profonde, comme la poplitée, le chirurgien est quelquefois fort embarassé."

These exceptions of Broca exactly correspond to those of our case, with the difference that, only being able to formulate a diagnosis from the symptoms, I did not hesitate to eliminate aneurism, for the artery being distended by extension of the articulation I was able to move the tumor about in the depths of the popliteal space. And this symptom being present I could not do otherwise than diagnose a solid tumor independent of the artery, though possibly it might be attached to it.

It is a mistake which is often made. But how could this mobility mislead us? The tumor was not as closely in the median line as I first had thought. The artery had undergone slight lateral displacement, so that the growth had been carried somewhat outward from elongation of the vessel, so that on extension of the leg it did not become fixed. Well, suppose that we had made a correct diagnosis: should we have treated it otherwise? Evidently not. Any other method would have had as its object the formation of coagula in the aneurismal sac, and this object may be said to have been already attained. We have therefore done well to operate. The patient will do well and in a month he will be able to leave the hospital completely cured.

LANDLADY—That snow-storm you have painted is wonderfully realistic! Daubleigh—It must be. A tramp got into my studio one day, caught sight of the picture, and unconsciously put on my fur overcoat before he went out.—*Tit-Bits.*

THERAPEUTIC SUGGESTIONS FROM FOREIGN JOURNALS.*

SALT-WATER BATHS IN OSTEOMALACIA.

Dr. Z. Pelczar (*La Semaine Médicale*, No. 61, 1894) has obtained excellent results, with baths, in a solution of common salt and water, in eleven cases of women in an advanced stage of osteomalacia. They ranged in age from twenty-five to forty-six years, multiparæ, in whom the affection had begun after a confinement and dated from two to eight years. The beginning, the chronic course, the pains and the deformations of the bones as well as the cutaneous hyperesthesia, exaggeration of the reflexes, the paretic state of the lower extremities, etc., without any cerebral or spinal symptoms, all permitted him to diagnose the disease with a certainty. In all the cases treatment consisted simply of salt-water baths containing from six to sixteen kilograms of common salt, according to the strength of the patient. They were at a temperature of 34° to 37° C., lasted from fifteen to thirty minutes and were repeated every day or at longer intervals, according to the tolerance of the patient. Besides this lime-water was administered in milk. After several baths they experienced relief; twenty baths sufficed to free them from their pains and to render their movements easier. At the end of four to eight weeks a notable amelioration was to be seen, and in several cases the osseous deformations had partly disappeared. He does not attempt to decide if the cure be lasting.

BROMOFORM IN MENTAL DISEASES.

Dr. Ponticaccia (*Wiener Medizinische Presse*, No. 41, 1894) recommends bromoform very highly in acute maniacal states. He begins the remedy with fifteen drops a day, which are divided into hourly doses, and increases it every day by five drops until from twenty to fifty drops are given a day. Employed in this manner it causes no disagreeable after-effects and in general does not influence the health beyond a slight diarrhœa which is easily controlled by opium. Its sedative action is always prompt and decisive, so that it need not be administered for more than fourteen consecutive days. He relates eight cases, accompanied by violet maniacal attacks, where the remedy gave him prompt results. The first one may be presented in full as an illustration of its action. A merchant of forty-one years and a habitual drinker was seized with a violent attack of delirium tremens, with great restlessness which persisted for twenty-four hours in spite of large doses of chloral hydrate. Therefore in the evening twenty-five drops of bromoform were prescribed, and in half an hour the patient was in a deep sleep with quiet and regular respiration, full and heavy pulse, normal heart's action and perspiring slightly. The following morning he awakened quietly with complete consciousness and only complained of slight headache and a feeling of heaviness in his head. In the course of the day he became still quieter. This improvement continued so that the following day there was no sign of restlessness nor at his discharge from the institution, six days later. From his experience the author concludes that the remedy in progressively increasing doses, twenty to fifty drops a day, in patients with delirium in combination with intense maniacal excitement, exerts a marked sedative action; that it does not act the same in all mental diseases, but it influences the symptoms, excitement and delirium. On the contrary, its action varies more according to the duration of the disease than its intensity, for it has a very favorable action in acute conditions and a less decided one in those having lasted for several months.

INTESTINAL ANTISEPSIS.

Prof. H. Huchard (*La Semaine Médicale*, No. 61, 1894) recommends as an intestinal antiseptic the following powder:

Benzo-naphthol	25	o ʒvj
Powdered charcoal	15	o ʒiv
Pancreatine	5	o ʒj¼

Sufficient for fifty powders. Four to six a day.

TERPINE IN CHRONIC BRONCHITIS.

Dr. Delmis (*Gazette des Hôpitaux*, No. 118, 1894) has employed terpine in chronic bronchitis, bronchiectasia and emphysema, as well as in phthisis, with successful results. It is best given in a pill of ten cgms., three to ten a day.

* In charge of the translator, F. H. Pritchard, M.D.

ELECTROLYSIS IN CHRONIC GONORRHŒA IN WOMEN.

Dr. Barthélémy (*Annales de Dermatologie,* Nos. 8, 9, 1894) has obtained good results with electrolysis in the treatment of gonorrhœa in women in cases which were even refractory to repeated curetting, as well as in chronic urethritis. He employs twenty Léclanché cells and applies from fifteen to twenty milliamperes for twenty-five to fifty seconds to the urethra, parurethral crypts and Bartholini's glands. In the uterus he allows forty to fifty milliamperes to act for three to four minutes. The positive pole is used as a cauterizant, while the negative is applied to the abdomen. In the uterus an ordinary uterine sound may be used, in the crypts a thin platinum wire. A sitting should be given every sixth day and the treatment be continued up to two months. He has never noticed any disagreeable results.

COCAINE TO SUPPRESS THE SECRETION OF MILK.

Dr. Iore (*Lo Sperimentale,* No. 30, 1894) having observed with other gynecologists that when cocaine is employed in painful fissures of the nipple it had the inconvenience of diminishing the lacteal secretion, concluded to employ it in those cases in which it was necessary to suppress this secretion completely. He uses a five per cent. solution in the following formula:

Muriate cocaine.....	5 | o	5j¼
Distilled water.....	āā 50 | o	5jss gtts xxx
Glycerine.....		

This solution is applied by means of a camel's-hair brush five or six times a day to the two nipples. The milk will be suppressed in two to six days. No inconvenience followed from its use on account of the small amount of surface to which it was applied. The cocaine prevents erection of the nipple, which according to Iore favors and maintains the lacteal secretion. [I have observed that the administration of the fluid extract of coca to nursing women will decrease the milk secretion. The quantity rises again to normal on discontinuing the drug.—*Trans.*]

TREATMENT OF ACUTE YELLOW ATROPHY OF THE LIVER.

Dr. X. Arsosan (*Norsk Magazin for Lægevidenskaben,* No. 10, 1894) communicates a case of acute yellow atrophy of the liver which he treated with success. Since the anatomico-pathological term acute yellow atrophy has been changed by bacteriologists to grave infectious icterus, the modes of its treatment have also altered, and the antiseptic method is regarded by Chauffard as the most promising. The writer proceeded as follows:

1. Absolute milk diet in order to spare the kidneys and facilitate elimination of the toxines.

2. Administration of the following intestinal antiseptic:

Sulphate quinine.....	āā o | 15	grs. ijss
Beta-naphthol.....		
Powdered charcoal...		

To be put up in capsules. Two capsules four times a day.

3. Hypodermic injections of carbolic acid, one-half a syringeful of a 2 per cent. solution daily.

4. Symptomatic employment of tonics, as alcohol, quinine, etc.

The injections of carbolic acid are especially indicated in violent delirium and high temperature, yet they should not be given during coma and prostration, low temperatures nor when there is a pronounced inclination to subcutaneous hemorrhages.

THYMOL AS AN ANTHELMINTIC.

In the *Hospitals-Tidende,* No. 41, 1894, thymol is spoken highly of in the treatment of intestinal parasites and in doses of one-half to two grams (grs. vijss–xxx). While the male fern will be generally preferred in tapeworms, thymol is the best remedy in pinworms when given in a rectal injection.

ICE IN TACHYCARDIA.

Dr. E. Isnel (*Revue Internationale de Medecin,* No. 18, 1894) claims that local application of an ice-bag to the precordium in tachycardia will increase the force of the heart-beat by acting directly upon the myocardium, augment the blood pressure, diminish the number of pulsations and cause irregularities in the heart's rhythm to disappear. Finally, it favors pulmonary circulation and respiration. [A recent English observer has reported an attack of tachycardia aborted by belladonna internally and galvanization of the pneumogastric nerve. A mustard plaster to the epigastrium with belladonna in-

ternally I have found serviceable in one case.—*Trans.*]

DENTAL NEURALGIA OF PREGNANT WOMEN.

Dr. Graetzer (*La Semaine Medicale*, No. 57, 1894) praises, in the dental neuralgic toothache of pregnancy, the following formula:

Acetanilid.....	o | 25	grs. iv
Phenacetine.....	o | 50	grs. viij

Sufficient for one powder. Make six such. One powder three times a day.

THE GALVANIC BRUSH IN SCIATICA.

Dr. Witkowski (*Muenchener Medicinische Wochenschrift*, No. 41, 1894) has obtained very good results with the galvanic brush in sciatica, which instrument he believes to be far superior to the ordinarily employed faradic brush in intensity of action, exactness of dosage and therapeutic efficacy. The patient is placed upon the abdomen and the skin over the sciatic nerve, in its whole extent from its point of exit to the terminal ramifications, is rubbed with the cathode, to which the slightly moistened brush is attached, for about five minutes, with a current of quite high intensity. The electrode is permitted to rest at times upon the painful points. These applications are repeated daily or every two days. The results, he claims, are actually brilliant even in inveterate cases which have resisted other methods of treatment. In some few cases it was necessary also to employ massage and stretching of the nerve. This latter is done by placing the patient upon the back and flexing the thigh forcibly upon the pelvis. The procedure is at first painful, but a notable amelioration is seen after a few trials. Also in tabes dorsalis the galvanic brush has yielded him excellent symptomatic results.

THE DANGERS OF THE IODIDES IN PHTHISIS.

Dr. V. Vitvitzky (*La Semaine Médicale*, No. 57, 1894), of Charkoff, Russia, has observed a case which goes to demonstrate the possible dangers of the iodides in the treatment of pulmonary tuberculosis. A woman of twenty years suffered from a cough with tickling in the larynx and painfulness on swallowing and presented suspicious signs in the apices of both lungs. Yet she had had no fever and her general health was excellent. A laryngoscopic examination showed the larynx to be greatly congested and the vocal cords ulcerated. As they were justly thought to be syphilitic, the iodide of ammonium was prescribed in a dose of two grams a day. After eight days of this treatment a manifest aggravation was noticed. The cough increased, her temperature rose, both râles and an intense bronchitic souffle were to be heard in the apices; bacilli were discovered in the sputa, which up to then had been without trace of them, and a complete picture of galloping consumption developed which was soon followed by death. As is known, a certain number of the symptoms of iodism are localized in the lungs and are expressed by cough, muco-serous expectoration and pleuritic pains. An abundant transudation of serum has been found in the lungs of dogs in which subcutaneous injections of a solution of iodine and the iodide of potash had been made. These facts go to prove that in certain cases of pulmonary tuberculosis the iodides will bring about an unfavorable congestion which may be followed by softening of the tubercles. [In doubtful cases it was suggested a few years ago to administer the iodide to develop the hidden foci of pulmonary tuberculosis if they were present.—*Trans.*]

PERMANGANATE OF POTASH IN POISONING BY PHOSPHORUS.

Dr. Kelemen (*La Semaine Médicale*, No. 57, 1894) was called to a woman two hours and a half after she had drunk a cup of water containing the heads of four boxes of matches. She was conscious, pale, with an intense pain in her stomach and a rapid pulse. He administered sulphate of copper as an emetic and followed this by a 1 per cent. solution of permanganate of potash, she ingesting a quart and a half in two hours and a pint in the rest of the day. The next day she was better but complained of severe pains in her stomach and she had vomited three times. From the fourth day the pains and vomiting ceased and in a few weeks she was well.

CONSULTATIONS IN FRACTURE CASES.

Perhaps, taken as a whole, there is no class of traumatisms which are apparently so simple and yet are oftener attended with unsatisfactory results than fractures of the extremities.

The average graduate in medicine on his entrance into general practice is apt to be engrossed solely with the nature of the bone lesion, the quality of the fracture—whether simple, compound or multiple, oblique, transverse, etc.—and unless he has had surgical experience or has been specially warned, his efforts will be primarily directed toward securing immediate reposition and immobilization of the fragments. The possibility of anchylosis following, or injuries of the nerves, the blood-trunks or muscles he may entirely overlook. He adjusts the dressings, splints, bandages or apparatus with an injunction that if severe pain is experienced morphine should be freely given. But the tight bandage has gotten in its deadly work and gangrene follows in the way of peripheral sloughs, or perchance the whole limb is doomed. The patient may recover without any marked deformity, but the limb is paralyzed or a joint is hopelessly locked together by anchylosis.

It is not generally known that with a limb, as with the whole body, violent concentrated force may kill it outright while there are no marked traces of mutilation externally visible to the eye.

The experienced surgeon in serious traumatisms will recognize this in an instant and will predict results accordingly. But with one who has not had opportunities to examine many of such cases, the chances are that he will commit the fatal error of immediately splinting; and when the black, cold foot or hand proclaims the death of the part and that mortification has commenced, he is invariably charged with having destroyed the limb.

What shall one do in the average case of fracture in order to avoid error? Clearly his first move should be to secure the aid of a consultant. He should do this to protect his own reputation, as well as

to fulfill his own obligation to his patient.

The sacrifice of a limb through the ignorance or carelessness of the surgical attendant is indeed a very serious matter, which the profession as well as the courts is always ready to condemn and punish. For however harsh it may seem to the unfortunate defendant, it should never be forgotten that when expert knowledge is called for, the testimony submitted should be solely in the interest of truth and justice, regardless of who is the sufferer in consequence.

These reflections have been suggested by the report of an interesting malpractice suit lately held in Ireland and published in the *Medical Times and Hospital Gazette* (November 17, 1894).

Dr. Thomas O'Brian was the defendant in the city of Cork assizes. The plaintiff was a young, able-bodied groom who had been thrown from a horse and sustained a fracture of the clavicle. Soon after dressings had been applied gangrene of the arm set in, and a shoulder-joint amputation had to be performed. Drs. Walsh and Hueston, of that city, on the stand stated that in their opinion the gangrene supervened in consequence of too tight bandaging; while Surgeon Wheeler, of Dublin, after hearing the testimony, testified that he believed that the gangrene was due to an injury of the subclavian vein at the time of accident. Mr. Nyles, of the Richmond Hospital, employed by the plaintiff, said that in the whole history of surgery rupture of the subclavian vein as a result of fracture had never occurred.

The plaintiff sued for £1,000, and it appears that the jury was satisfied that the doctor was blamable, for they brought in a verdict against him for £175 damages.

We do not learn whether Dr. O'Brian had any associate with him in the early attendance on the case.

If a practitioner fears that he will suffer in prestige or begrudges a consultation fee to a competent *confrère*, then if his case goes badly he should be expected to solely bear the consequences; for the profession is under no obligation to shield him from the full rigor of the law.

ABSTRACTS.

ETIOLOGY AND PROPHYLAXIS OF DIPHTHERIA.

Dr. Becker, of Toledo, Ohio, related the following:

Loeffler, from Greifswald in Germany, says that diphtheria is produced by a specific bacillus, whose importance is not doubted any more by anybody. As diphtheria we can consider that affection only which is produced by the Loeffler bacillus, excluding all similar affections which are caused by other microörganisms. In fact, we often find diseases of the upper air passages which give the same picture as genuine diphtheria, but which are caused by an infection of streptococci, staphylococci or pneumococci and which, like the genuine diphtheria, can take a benign or malignant course. The differentiation in diagnosis can only be made by bacteriologic examination, and all the statistics of diphtheria cannot have any value as long as this differentiation is not strictly observed.

The course of an epidemic diphtheria depends on different factors: (1) on the quantity and the virulence of the diphtheritic bacilli; (2) on mixed infections by which the virulence of the bacilli is increased or the organism weakened by the absorption of the products of secretion; (3) on the individual predisposition.

The bacillus of diphtheria is often found in the pharynx or in the nose of healthy individuals, its presence not producing any pathologic symptoms. It produces a disease only in those cases in which it is fixed on the mucous membranes. Lesions of the mucous membrane facilitate this fixation, and atmospheric

changes, moist air, etc., seem to favor the development of the disease. In the majority of the cases diphtheria is directly transmitted by contact, by cough, kisses, by hands which are soiled with the fresh secretion, but often also by food, linen, etc., even a long time after the infection.

The patient must be considered as dangerous to others as long as bacilli can be found upon the mucous membrane. Usually they disappear a short time after the healing of the local process, while in certain cases pathogenic bacilli are found in the pharynx and the nose after weeks. Enveloped in organic substances and with the exclusion of light the bacillus can retain its activity for months outside of the organism. Dirt, moist and dark houses therefore favorably affect the conservation of the bacilli and the spreading of the disease. The most favorable condition for such a spreading is found in accumulations of susceptible individuals, as in schools, etc.

As means of prophylaxis are especially recommended:

1. Cleanliness, dryness, ventilation and light of residences.

2. Hygiene of the mouth and nose; repeated gargarisms with solutions of chlorid of sodium or bicarbonate of soda; cleanliness of teeth, extraction of diseased teeth; removal of hypertrophied tonsils.

3. Cold spongings of the neck.

Every suspicious case should bacteriologically be examined. Every practitioner should receive culture media from drug stores or health offices to be simply inoculated and sent to the bacteriologic station. The report of all cases of genuine diphtheria, likewise of all suspicious cases, should be obligatory, and all the diphtheritic patients should be isolated. To possibly prevent the spreading of pathogenic germs, local anti-parasitic treatment should be resorted to if the locality of the disease allows it.

The most effective preventive against the spreading of diphtheria is the prophylactic inoculation of those persons surrounding the patient, especially of the children. Numerous experiments have proven the harmlessness of Behring's curative serum (Heilserum), and its effect as a preventive remedy should be tested liberally in schools and families. Disinfection of the sick-room and of all things which have been used by the patient should always be done. Convalescents from diphtheria should not come in contact with healthy people before the absence of the bacillus is proven by bacteriologic examination. In epidemics the laity should be enlightened by public instruction and publications.

Representing the French Committee, Professor Roux, from Paris, offered the following thesis:

1. Diphtheria is a contagious disease; the report of the cases must be obligatory.

2. Diphtheritic patients should be isolated.

3. The health officers have to provide for the proper disinfection of rooms infected by diphtheritic patients, of their clothes, linen and beddings; in short, of everything that has been used by the patients, toys included. During the sickness the soiled linen, etc., must be disinfected before given out for washing.

4. Carriages, etc., used for the transportation of diphtheritic patients must be disinfected after each use.

5. Children who have had diphtheria should be kept from school until the physician has stated the cure and permitted the return to school.

6. When a pupil of a certain school is taken sick with diphtheria, the rest of the children should be under the observation of a physician for some time. All suspicious cases of angina should be excluded from school immediately. Special care is required for the sisters and brothers of a patient.

Besides these rules, to be effected by official ordinance, the following principles should be generally adopted:

1. In order to employ an effective treatment of diphtheria the diagnosis must be made early. The beginning of the disease is insidious in many cases, and it would be overlooked less often by frequently repeated inspection of the child's pharynx. Mothers should make this inspection daily and the children be made used to it from an early age.

2. An early and sure diagnosis of diphtheria can only be made by bacteriologic examination, which therefore should be practiced by every physician.

3. Our knowledge concerning the effect of the anti-diphtheritic serum is of a kind at present that its prophylactic use can be recommended for children in families with a diphtheritic case.—*The Journal.*

PREVENTION OF DIPHTHERIA FROM THE STANDPOINT OF THE HEALTH OFFICER.*

U. O. B. WINGATE, M.D., M.M.S.S.

In presenting this short paper I do not claim to offer anything original or new, but merely to give the results of my observations and suggest points that may be profitably discussed.

Prevalence.—The widespread and variable prevalence of diphtheria is of great interest to the health officer. Rural statistics avail us nothing in this country, as a rule, but statistics of death from this disease in our larger cities are fairly reliable. There is one feature, however, that has not yet generally entered into our statistics that may modify them somewhat, that is, the prevalence of croup and what proportion of cases of so-called membranous croup are cases of diphtheria. The recent researches of Dr. H. M. Biggs, of New York, which show that nearly 80 per cent. of cases of so-called membranous croup were found to be cases of true diphtheria by a bacteriologic examination, are of great importance to the health officer and demand a most earnest and careful consideration. I believe all cases of croup presenting exudation in the throat should be treated by the health officer as true diphtheria, unless a bacteriologic examination proves it to be non-diphtheritic. This would seem to be, in our present state of knowledge, the only safe procedure, for certainly if there be a doubt in regard to the care and treatment of infectious diseases the public should have the benefit of it.

The following is a table showing the per cent. of deaths from diphtheria on the estimated population during the years 1892 and 1893, as officially received from a few of our larger cities in this country:

New York	1892	0.08	1893	0.10
Chicago	"	0.07	"	0.06
Philadelphia	"	0.13	"	0.08
Brooklyn	"	0.08	"	0.06
St. Louis	"	0.04	"	0.04
Boston	"	0.09	"	0.10
Baltimore	"	0.08	"	0.04
San Francisco	"	0.07	"	0.05
Cincinnati	"	0.09	"	0.05
Buffalo	"	0.06	"	0.05
Cleveland	"	0.07	"	0.04
Washington	"	0.07	"	0.04
Pittsburg	"	0.11	"	0.06
Milwaukee	"	0.16	"	0.08
New Orleans	"	0.02	"	0.03

It will be observed by this table that in 1892 the largest death-rate from this disease in fifteen of our largest cities was in Milwaukee, Philadelphia and Pittsburg, being 0.16, 0.13 and 0.11 respectively; and the smallest rate for the same year was in New Orleans, St. Louis and Buffalo, being 0.02, 0.04 and 0.06 respectively. While in 1893 the largest rate was in New York, Boston and Milwaukee, being 0.10, 0.10 and 0.08 respectively; and the smallest rate was in New Orleans, Washington, Cleveland, Baltimore and St. Louis, being 0.03, 0.04, 0.04, 0.04 and 0.04 respectively. These figures are approximately correct.

Etiology.—That the Klebs-Loeffler bacillus and its products cause all the pathologic phenomena connected with diphtheria there seems to be no reasonable doubt at the present time, but the origin of this bacillus and its habits are matters far from being settled, and these questions bear a very important relation to the etiology of this disease. Whether the bacillus originates *de novo*, or whether it is a product of evolution from other forms of life, whether it can live in the soil in its true state or is capable of taking on a form of existence non-pathogenic or saprophytic for an indefinite period of time, and then under certain favorable circumstances is capable of developing into pathogenic qualities, are questions yet to be solved. Quite an extensive experience with this disease, both as a practicing physician and as a health officer in a city which at times has led all other cities in this country in the large number of cases of diphtheria, leads me to observe that it is favored by cold, damp, cloudy weather; that it is more active in winter than in summer; that it is favored by damp, dark cellars and poorly drained soil; that in certain conditions of soil and weather it seems to remain dormant for an indefinite period of time, and under more favorable conditions, such as cold, cloudy, damp but not too wet weather, it becomes active; that sunlight, good air, good drainage and plenty of snow in its season very materially lessen its ravages. There is much, however, to be learned concerning the true nature and habits of this bacillus, and

*Read in the Section on State Medicine, at the Forty-fifth Annual Meeting of the American Medical Association, held at San Francisco, June 5–8, 1894.

this is a difficult matter to study, for nature's laboratory, in which these bacilli operate, is far different from any constructed by man.

That defective plumbing may be an indirect cause there seems to be no reason to doubt, but I have found no evidence that the bacillus is carried in the escaping sewer air; it is more probable that the effect of inhaling the sewer air debilitates the system and renders the powers of resistance less, thereby favoring the infection of diphtheria as well as any and all other infectious diseases.

Periodicity.—Hirsch has called attention to the possible cyclical character of the epidemicity of this disease, though the cycles have extended over periods of various lengths, many of them only a few years, others lasting several decades. In the city where I reside, the two periods of greatest prevalence of the disease that have existed since records have been kept were about ten years apart, these periods lasting about two years each; at other times, although the disease has been constantly present the number of cases has been comparatively low.

Modes of Dissemination.—The means of disseminating this disease are many; from person to person by means of infected clothing of all kinds, furniture, rooms, books, papers, foods, drinks (especially milk), milk tickets, money, domestic animals, such as dogs, cats, birds, etc., and at school from everything with which the child may come in contact, as almost everything conceivable may, under certain circumstances, become infected. There is no evidence that the disease can be disseminated by the air for more than a very few feet; it is usually necessary to come in actual contact with the bacillus at its lodging-place in order to become infected, and unless it is propelled for some little distance by the patient in coughing, it is rarely taken through the medium of the atmosphere.

Stage of Incubation.—The stage of incubation is usually short, not longer than two or three days; it may vary, however, being modified by the virulence or activity of the bacilli and the powers of resistance offered by the patient.

Prevention and Control of Epidemics.—In ordinary communities the health officer must first have great legal powers, and they must be executed if he is going to contend with this disease; he must also have the hearty coöperation of all physicians in the vicinity. Without these two requisites he is absolutely powerless. The education of the people in the importance of sanitary matters is an admirable requisition, but it will not be sufficient alone, in our day and time, to cope with epidemics of diseases of any kind. The importance of law and the coöperation of physicians cannot be too highly appreciated by members of our own profession. Our medical schools need to impress this more emphatically on the minds of medical students.

Cases must be isolated early and long, and to do this in most families where the disease prevails, the cases must be reported to the health officers early. Every city and town should provide means for a bacteriological examination in any and all cases where there can be a question of doubt about the diagnosis, and this is often the case.

Every city and town should also be provided with an isolation hospital, or an isolation ward in a hospital, to which every case can be removed, if possible, and isolated from all other cases and placed under the charge of nurses trained in the care of infectious diseases. By these means a better chance of recovery is gained by the patient and the danger of spreading the disease is reduced to a minimum. These facts should be taught the people by the physicians in such earnestness that they cannot fail to learn the lesson. These hospitals should not be pest-houses nor disgraced by that name. Under modern scientific medical knowledge we have no longer any use for a pest-house, and one should not be tolerated in any civilized community. With the antiseptic and aseptic care of all patients with diphtheria, as carried out by modern trained nurses under the direction of competent physicians, in properly constructed isolated hospitals, the control of the infection is absolute. A case of diphtheria early diagnosed and removed to an isolation hospital, and kept there until fully recovered or until he dies and the body properly disposed of, and the house and infected articles in the house early and properly disinfected or destroyed by fire if of little or no value, will prevent a spread of diphtheria as effectually and surely as a problem can be solved in mathematics; but the details in each case must be correctly observed to ar-

rive at a successful result. Where a large number of cases exist in a community the same principles hold good, but it becomes a more complicated problem.

Isolation and disinfection are the keynotes of the prevention and spread of diphtheria, but the details of these two important measures must be as fully understood, and their importance as fully realized, in order to be successful, as the principles of asepsis in surgery.

Having isolated the patient and thoroughly disinfected all apartments and articles infected, and having cared for the case in the most approved manner known to modern trained nursing, there is one matter often lost sight of, that is, keeping the patient isolated long enough. It is well known that the bacilli of this disease may exist in the posterior naris and pharynx for a long time after all traces of exudation have disappeared, and it is decidedly unsafe to discharge patients from isolation until the mucous membrane is entirely healthy and has been thoroughly disinfected for several days after all appearance of a diseased condition has subsided.

No case, however light, should be discharged from isolation for at least four weeks from the time of the commencement of the disease, and no child should be allowed to attend school or mingle with other children until the expiration of six weeks from the commencement of the last case in a house, in case of recovery, and in many instances a much longer period of time should be observed. In case of death, the body should be wrapped in a sheet wet in a proper disinfectant and immediately hermetically sealed, and should be prohibited from transportation, but should be buried or cremated within twelve hours after death, after which all apartments and articles infected should be thoroughly disinfected, and those of the family exposed should not be relieved from quarantine for at least seven days after the disposal of the body and disinfection. This rule should also apply to all persons exposed to a case of diphtheria before thorough isolation and disinfection, whether isolated at home or removed to a hospital.

By such measures only can we expect to control the ravages of this disease, and it will require a realizing sense of the importance of such measures on the part of the health officer, as well as courage and efficient police powers and police force, at times, to carry out such provisions successfully.—*The Journal.*

OVER-FED INFANTS; CAUSE, EFFECT, TREATMENT.

Work (*Jour. A. M. A.*) says: We can say properly that an infant is over-fed when it fails to digest and assimilate the food furnished it. The natural food of the new-born babe, all things being equal, is the food sent with it—the mother's milk—which for the first two or three days after birth seems to the inexperienced or unthinking mother or nurse very inadequate to the support of the child, but it is all that the little new creature can possibly, with certainty, digest and assimilate. Too often the mischief is played with the child during the initiatory period of its digestion. It is often difficult for the attendants in the nursery to realize or understand the untried weak condition of the whole digestive and correlative systems of the infant. In fact, we must consider that the whole new being with all its varied systems, both anatomic and physiologic, is in a primary rudimentary condition. Thus we observe the simplest form of food which is naturally furnished it. Recognizing the foregoing fact, we should act intelligently if we are called upon to advise in artificial feeding, and select that food for the unfortunate infant which most nearly simulates the mother's milk. Unless disease is present with the mother, which is transmissible by her milk to the child, we should use our utmost endeavor to have it nurse the mother; as we have the best interests of both mother and child in view.

Some young mothers do not possess the best facilities for furnishing this natural food to their offspring, but there are very few who cannot be corrected in this respect by patient persistence. If the nipple is not drawn to dimensions sufficient to allow the babe to nurse well during the first two or three days after parturition, we may have to resort, unfortunately, to artificial feeding; for after lactation proper ensues there is usually such a tur-

gescence of the mamma that satisfactory modification of the nipple then is impossible, and after the usual application of pumps, plasters and various ointments to remove this gorged condition, the babe is virtually weaned; and if the child is so fortunate as to get its natural food, unless regular habits of feeding during the initiatory stage are observed, it is in danger, when lactation proper ensues, of overfeeding or being over-fed. There is a great temptation often on the part of the mother, which is largely selfish, to make a breast pump of her child, and thus its stomach is impaired. If normal regular habits as to nursing are well established, on the part of the child, commencing immediately after birth, which habit we know can be attained within seventy-two hours by allowing the child its own undisturbed time to rest or sleep, after first attending to all its needs as to proper cleansing, clothing and food, if it demands it, before tucking it in its little bed in a warm, properly ventilated nursery, allowing it to awake by force of hunger or some other cause peculiar to itself—some dictate of nature. When it awakes give it such care as will make it comfortable for another period of rest of from two to six hours, then put it to the breast again to its satisfaction. It may nurse itself asleep; then tuck it away again, and so on, and we can truly say it is a natural child, following natural habits of life. And, too, the mother by this habit of the child will find that the supply of food will adjust itself to the needs of the child, and by a little common sense on the part of all concerned in the care of the little one, there will be no danger of overfeeding and bringing on the invariable result, viz., indigestion, bad assimilation and perchance cholera infantum.

The result of over-feeding is the leading factor in the very great mortality in infancy and childhood. It is true that quality of food plays an important part in the ailments of children. Even in considering the zymotic diseases of children, by which diseases so often fond hopes are blighted, we must admit that the mortality is largely due to over-feeding prior to the inception of the disease. The disease is severe or not according to the fermented condition of contents of the alimentary tract. The decomposed contents of the *primæ viæ* is a fertile field for the rapid propagation of bacilli or disease germs. Thus the severe form of the disease.

The incontrovertible law of cause and effect holds good in the consideration of our subject as well as in all things else with which we have to do. Not long since I was called to the bedside of a child twenty months old, who was feverish, emaciated and debilitated, even to inability to close its eyes; could scarcely utter a cry, had frequent curdy stools and vomited sour curd occasionally. Disease had been denominated cholera infantum. On inquiry of the mother I learned that the child had been sick at intervals for twelve months, and suffered similarly as at this time. Had employed four physicians during this period; child was weaned from its mother, and I learned that she was instructed to give it all the cow's milk it wanted and whenever it wanted it. The case required but little study to determine a diagnosis; cause, over-feeding; effect, the condition of child as above delineated. Before consenting to treat the case, I had the mother promise to follow my directions strictly. We all know how often a mother's sympathy or affections run away with her judgment and thus our directions are not followed, and the result is not satisfactory to either friends of patient or doctor. I ordered three teaspoonfuls of good fresh cow's milk (cow was in the barn near by) every three hours, preceded by a weak solution of bicarb. potassium and followed by two or three grains of catalysin and carbon. This treatment was to continue for twelve hours, and if vomiting ceased and stools less frequent, or change for the better, they were to give four teaspoonfuls at a time, and so on, as the child improved in its digestion and assimilation. We increased the amount of milk until twelve or fifteen drachms were given at a time, which was enough to cause the child to improve so that in four days I pronounced it well, and only had to advise temperate feeding.

Over-feeding the infant and the result following *directly* renders the system less resistant to the diseases of childhood and, in fact, may be a menace to its well-being throughout even a long life. On the other hand, if wisdom is used in following the dictates of nature (as God intended we should) in the feeding of infants, the foundation is laid, physically, for a long and useful life.

THE LIBRARY TABLE.

BOOK REVIEWS.

SYPHILIS IN THE INNOCENT (SYPHILIS INSONTIUM). Clinically and Historically Considered, with a Plan for the Legal Control of the Disease. By Duncan Bulkley, A.M., M.D., Professor of Dermatology New York Post-Graduate Medical College; Physician to the New York Skin and Cancer Hospital, etc., etc. 8vo, 398 pages. New York: Bailey & Fairchild, publishers, 29 Park Row.

One critic has said that after reading this book one feels that even if he were an anchorite, living in the midst of the desert, he could not escape the ravages of the syphilis. While this may be true to a certain extent, the work is a very valuable one, showing as it does the modes by which the scourge can be transmitted in the routine of social and industrial duties to those who are leading perfectly pure lives. Fully one-half of the volume is taken up with an analytical bibliography, for which the highest praise must be accorded the author for his painstaking toil and the vast amount of labor necessary for its compilation. Tables are given of all the epidemics of syphilis, and also one including over nine thousand cases of extra-genital infection, besides which there is the record of over one hundred cases observed by the author himself.

Almost every article of common use is shown to be possible of carrying the contagion. Pipes, spoons, cups, bank-notes, even speaking-tubes, are shown to have communicated the plague. The bathing-robe from a public bath-house is responsible in two cases cited. There is hardly anything which is not shown to be a carrier of the poison, though it is curious to note that the water-closet, so often alleged by patients to be the source of infection, has only six cases credited to it, and some of these are so old and so briefly mentioned by those reporting them as to be of little scientific value. One of the curious cases reported is where wash-water transmitted the virus. Saddest of all are those instances where the physician, while engaged in his work of alleviating suffering, has conveyed the disease or himself fallen a victim.

The question of the legal control of syphilis is one to which the author has evidently given much thought. To quote from the work: "The subject of prostitution becomes a secondary consideration. The first question is not one of 'regulating prostitution' or of inspecting, licensing or legalizing the 'social evil' or of protecting those engaged in it. The legal control of syphilis has a much higher aim, namely, the prevention of the unnecessary extension of a disease which produces a vast amount of sickness, misery and death, not only among the guilty, but also among the perfectly innocent." The author urges that syphilis can be checked in its spread and that "the time has come to place it under the control of the proper health officers, and to make it quite as *criminal to transmit syphilis wittingly* as it is to communicate small-pox, scarlatina or diphtheria." This plan, the author thinks, would act advantageously in various directions. The keepers of immoral resorts would see to it that the inmates were free from disease in order that action should not be brought against them. Moreover, they would take pains that the disease was not carried into the houses of ill-repute by the males frequenting them. Herein lies the important point of the author's argument: "Instead of examining the women publicly, those connected with the nefarious business would see that they were already in a healthy condition. They would then *examine the men.*" This, he believes, would deter men from entering a house of prostitution if they knew that they would have to submit to such an examination, and those who were syphilitic would exclude themselves. He also thinks that it would act to a greater or less extent against clandestine prostitution, as it would be recognized that among this class the dangers of infection were greater and the men would fear the legal penalties if they infected others outside. Such a law would, therefore, in the author's belief, diminish the frequency of syphilis and would also be a step in the direction of breaking up licentiousness.

One cannot read this chapter without being struck with the force of the argument—the placing of the disease on the contagious list and the consequent necessity of *examining the men instead of the women.* The author thinks that the plan would be free from the objections always raised by a certain proportion of the community against the legalization of prostitution and the degrading influences of police inspection, though he confesses that much enlightenment and education on the part of the public is imperative before any method can be adopted for the check of the slow but steady increase of syphilis which is taking place.

The essay which is the foundation of the present work was deservedly awarded the Alvarenga Prize of the College of Physicians of Philadelphia, and while the book is of particular interest to the specialist, it is also so to the practitioner of general medicine as opening his eyes to the ravages of the disease among those whom he may have least cause to suspect and in whose lives there exists not the least shadow of wrong-doing. That it is one of the most exhaustive works which has ever been made of any one medical subject is not too much to say of it. E. J. M.

A MANUAL OF MODERN SURGERY, GENERAL AND OPERATIVE. By John Chalmers DaCosta, M.D. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

At the present time there is demand for a book on the subject of surgery which shall stand midway between the quiz compend and the large text-book. This want the author has succeeded in filling; for he has produced a book which, though brief, is clear in style and clever in description.

In the chapter on bacteriology the author readily and without comment accepts as truths theories which the experience of the profession has not as yet shown to be absolutely correct. He follows the school of Metschnikoff rather than of Koch, the leader of thought in the bacteriological world.

The chapters on fractures and dislocations are very long in proportion to the size of the book, for the author wisely decides that as these form so important a part of the work of the surgeon they are worthy of considerable discussion.

In the chapter on abdominal surgery full and accurate directions are given by means of which the small intestine can be differentiated from the large bowel, the most important being in the difference between the attachment of the mesentery and the meso-colon.

The directions for anæsthesia and its complications are clear and explicit and surpass those found in the ordinary text-book on surgery.

Ophthalmology, gynæcology, rhinology, otology and laryngology are not treated, because the writer considers that as these are special branches of surgery they should only be treated by the specialist. O.

LOCAL ANÆSTHETICS AND COCAINE ANALGÆSIA: THEIR USES AND LIMITATIONS. By Thomas H. Manley, A.M., M.D. St. Louis: J. H. Chambers & Co. 1894.

This unique and excellent monograph is the result of the author's long experience with local anæsthetics. All his statements are corroborated by cases cited from his own practice. He prefers local anæsthesia in the great majority of surgical cases, because it avoids all the deleterious after-effects of pulmonary anæsthesia. In his operations on the skull he prefers cocaine to ether, because under ether cerebral hyperæmia is produced which causes the brain and its membranes to protrude through the opening in the skull—a complication which is not met with under cocaine.

In hernia operations the mortality is decreased from 50 per cent., the ordinary rate, to 30 per cent. The large mortality in strangulated hernia he explains as follows: "Pain is a cardiac depressant of great potency, and when intensely poignant and long-continued induces deep collapse. Now it is well known that all pulmonary anæsthetics first stimulate and consecutively depress. Hence it may be in many cases of operation for strangulation ending mortally that the accumulative depression following the primary pain and the volatile chemical was too great for the recuperative powers of nature to overcome."

He has used thermal anæsthesia extensively in breaking up fibrous anchyloses.

He gives accurate directions for the use of cocaine hypodermically, preferring the "hub-and-spoke" method, which consists of one insertion of the needle and, after withdrawing it slightly, inserting it through the same opening in different directions under the skin.

As this monograph embodies the results of many cases, the whole profession would do well to read it and learn some of the remarkable results that can be obtained by the use of local anæsthetics and the avoidance of all the disagreeable after-effects of pulmonary anæsthesia.

A SYNOPSIS OF THE PRACTICE OF MEDICINE. By William Blair Stewart, A.M., M.D.

The usual classification of diseases is adopted by the author, who has described in a concise manner everything relating to the practice of medicine.

Under the head of "Prophylaxis of Contagious Diseases" the author has made a serious mistake by recommending as a disinfectant a certain proprietary article of doubtful value. The profession is decidedly opposed to advertising patent preparations in the context of a book relating to medicine.

Appendicitis as such is not mentioned, but instead we have described typhlitis and perityphlitis, "terms which no longer imply pathological entities and are in most instances well relegated to obscurity."

That portion of the book relating to diseases of the blood, especially the anæmias, is carelessly written, for by following the author's description of the relation of the hæmoglobin to the red blood corpuscle, it would be impossible to differentiate between pernicious anæmia and chlorosis.

The chapters devoted to the fevers, infectious diseases and diseases of the respiratory tract are very clear and explicit and indicate a thorough knowledge of the subject.

As a whole the book is of a character to recommend itself to the student and the busy practitióner. J. O.

CLINICAL MEDICINE. By Judson S. Bury, M.D. Lond., F.R.C.P. London: Charles Griffin & Co., Limited. Philadelphia: J. B. Lippincott Company. 1894.

This work, which is designed for the use of students and young practitioners, consists of twelve chapters, as follow:

I. Introductory.
II. Symptoms for the most part subjective in character.
III. Examination of the surface of the body.
IV. Temperature.
V. Examination of the skin and its appendages.
VI. Examination of the respiratory system.
VII. Examination of the circulatory system.
VIII. Examination of the blood.
IX. Examination of the digestive system and the abdominal organs.
X. Examination of the urine.
XI. Examination of the puncture fluids.
XII. Examination of the nervous system.

The chapters devoted to the circulatory and respiratory systems are well written, but those parts relating to the blood and the urine are deplorably neglected. No method is given for the determination of sodium chloride. Boettcher's (bismuth) test, which is so frequently mentioned in the books as a counter-test for glucose, is also omitted. The

volumetric (Liebig's) method for the determination of urea, which can so readily be performed, is not described, but is stated as being inconvenient. The antiquated Gowers' hæmoglobinometer and hæmacytometer are preferred to the modern Thoma-Zeiss hæmacytometer and the Fleischel hæmoglobinometer, which are not even mentioned by name.

The chapter on nervous diseases is accurately written and harmonizes with modern teachings. With very few exceptions the book is exceeding accurate and can be relied on. J. O.

THE ETIOLOGY OF OSSEOUS DEFORMITIES OF THE HEAD, FACE, JAWS AND TEETH. By Eugene S. Talbot, M.D., D.D.S. Third edition. Chicago: The W. T. Keener Company, 96 Washington Street. 1894.

Between the covers of this book there has been gathered together a large amount of data concerning the irregular development of the bony part of the head, which has been worked out from collections of skulls representing the peculiarities not only of races but also of classes.

The subject of the jaw comprises a broad field of observation, proving the distinct association of this part of the human body with the brain and nervous centers and likewise with the character and hereditary tendency of the individual.

Among the criminal classes and those of neurotic tendency there is a much greater proportion of irregularities in development about the head than is found among moral and healthy-minded individuals. Besides establishing these facts as to abnormalities of cranial development, an effort has been made to determine the normal condition of the height of the palatine arch and the distance between the first molars of the upper jaw.

The author has departed from his immediate professional work and entered the new field of anthropology, in which so far he has been eminently successful, judging from the results of his work.

SYLLABUS OF THE OBSTETRICAL LECTURES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA. By Richard C. Norris, A.M., M.D. Third edition. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

The author in the preface to the first edition states his hope that the book may be of service to the medical student.

This hope has apparently been gratified, for we have before us the third edition.

The book is a syllabus of a series of didactic lectures, which are much condensed without in the least impairing their usefulness.

It does not pretend to obviate regular attendance upon the lectures, but seeks to aid the student in the difficulties of taking useful notes.

This edition is brought up to date by the addition of such new material as has appeared in the course during the last two years.

INTERNATIONAL CLINICS: A QUARTERLY OF CLINICAL LECTURES ON MEDICINE, NEUROLOGY, SURGERY, GENITO-URINARY SURGERY, GYNÆCOLOGY, OBSTETRICS, OPHTHALMOLOGY, LARYNGOLOGY, PHARYNGOLOGY, RHINOLOGY, OTOLOGY AND DERMATOLOGY. Edited by Judson Daland, M.D.; J. Mitchell Bruce, M.D., F.R.C.P.; David W. Finlay, M.D., F.R.C.P. Volume iii. Fourth series. 1894. Philadelphia: J. B. Lippincott Company.

This volume is the third of an interesting series. It contains forty-seven articles, which are reproductions of many clinics and comprise almost every disease to which the human flesh is heir. The papers not only represent what clinical professors say about their cases, but also what they do.

Any one who wishes to keep up with modern clinical methods cannot readily afford to be without this quarterly journal.

There are three articles devoted to the interesting subject of diabetes which are written by specialists on that subject.

The clinic of Roswell Park, of Buffalo, on the subject of "Perineal Section Following Suprapubic Cystotomy and Hernia," is very good. A. D. Rockwell's article on "Neurasthenia Versus Lithæmia" is also worthy of consideration.

The clinics of the German authorities are excellent, but the translations are very unsatisfactory.

HOME TREATMENT FOR CATARRHS AND COLDS. By Leonard A. Dessar, M.D. New York: Home Series Publishing Company. 1894.

This little handbook has been written with the idea of providing the laity with knowledge of how to take care of colds and kindred affections. In very simple language the principal affections of the ear, nose and throat are described, together with the remedies which are usually employed by physicians in such cases. What makes the book valuable to the ordinary reader is the entire absence of technical terms and the simple manner of description. O.

A MANUAL OF THE PRACTICE OF MEDICINE. By A. A. Stevens, A.M., M.D. Third edition. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

The author has not tried to furnish the profession or the student with a new work on the practice of medicine. He has simply collected from the ponderous text-books the most important facts and arranged them in a readily assimilable manner, using his broad experience as a teacher in the medical schools to guide him in his work. He has thrown out all theories and unnecessary explanations and has gathered together in a manual a useful outline of the practice of medicine.

ESSENTIALS OF DISEASES OF THE SKIN. By Henry W. Stelwagon, M.D., Ph.D. Philadelphia: W. B. Saunders, 925 Walnut Street. 1894.

That this compend, which is indeed carefully written, has reached a third edition is evidence that it has at least found favor among that class of medical students who desire to take a short cut to knowledge. "A

little knowledge is a dangerous thing," and the student who relies on quiz compends or manuals for his medical education gets the "little knowledge" which will make him dangerous as a physician later on in life.

SYLLABUS OF LECTURES ON HUMAN EMBRYOLOGY. By Walter Porter Manton, M.D: Philadelphia: The F. A. Davis Company, publishers. 1894.

The object of this syllabus is to furnish to students and practitioners the main facts of embryology. It follows the teachings of such authorities as Balfour and Foster, and harmonizes with the latest English edition of Gray's "Anatomy." Therefore it is to be considered as being trustworthy.

FIRST AID TO THE INJURED. By E. J. Lawless, M.D. Philadelphia: J. B. Lippincott Company. 1894.

This book has for its object the instruction of those who act in emergencies on the battle-field and in military camps. The chapters devoted to hemorrhage, fractures and wounds are concise and reliable, and for the treatment of these conditions minute descriptions are given, involving the use of such materials as are found in the hands of every soldier.

THE POCKET ANATOMIST. By C. Henri Leonard, A.M., M.D. Eighteenth revised edition. Detroit: The Illustrated Medical Journal Company, publishers.

This pocket anatomist is really Gray boiled down and condensed into the very smallest space possible. It is only intended as a help to the student in his preparation for an examination in anatomy, and as such is well executed.

A MANUAL OF HUMAN PHYSIOLOGY. By Joseph H. Raymond, A.M., M.D. One hundred and two illustrations in the text and four full-page colored plates. Philadelphia: W. B. Saunders. 1894.

This book is clearly printed and neatly bound; covers the subject at length in an interesting style and with sufficiently minute detail for any purpose except the preparation of a medical student for final examination on the subject, and would be a help even then. W.

PRACTICAL MANUAL OF THE DISEASES OF WOMEN AND UTERINE THERAPEUTICS. By H. Macnaughton-Jones, M.D., M.Ch., M.A.D. (Hon. Caus.). Sixth edition. London, England: Balliere, Tindall & Cox, 20 King William Street, Strand.

The book commends itself alike to the gynæcologist as well as the student, for there is much in it of interest to both. This edition, as compared with the other editions, is a comparatively new book, for it has been in greater part rewritten and is completely rearranged and reillustrated. Considerable additions have been made, especially in the pathological and surgical portions, to keep pace with the rapid advancement in those branches of gynæcology. Several new chapters on uterine reflexes, sutures and ligatures, the surgical treatment of uterine fibromata, affections of the Fallopian tubes, tubal pregnancy and ovarian affections have been added. The type is good, the engravings clear and the book compact. Altogether this volume will be "found useful as a safe guide by the practitioner and an assistance in the study of this branch of his profession by the student." W. C. G.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE PHYSICIAN AND SURGEON

for October. Dr. Don. M. Campbell writes of

The Surgical Treatment of Granular Conjunctivitis: A Modified Instrument.

Giving a long list of synonyms, the author states that the disease is very rebellious to treatment and often baffles even a specialist. A long list of remedies highly praised by various men is given and appears to divide itself into (1) astringents, irritants and caustics; (2) antiseptics.

The disease appears due to specific organisms causing the growth of the trachoma, deposits of lymphoid tissue in the inflamed conjunctiva.

The micro-organism growing in these granules makes their crushing necessary before we can destroy the growth.

While rasping, excision, etc., have been successfully used, the best means of treatment seems to be by Knapp's roller forceps, and as the pattern generally made permits a portion of the membrane to escape uncrushed, the author uses a modification, which he pictures, in which the rollers project beyond the jaws of the forceps.

Crushing is not sufficient, however, and after performing the operation nitrate of silver, sulphate of copper or bichloride of mercury should be applied in crystal or in solution, as seems best suited to the case, until cure results.

The cases reported where a single application of any kind results in complete cure generally are proven to have been simply papillary conjunctivitis.

Dr. Delos L. Parker writes of

Singultus.

Four cases are given of hiccoughing which resisted ordinary remedies. In one instance

the patient was suddenly seized when in seemingly good health; another was convalescing from dysentery; a third was dying from tuberculosis; and the particulars of a fourth case are not given. In each case cupping the epigastrium gave immediate relief, and in each case it was necessary to repeat the operation in two hours, but not again. The recurrence in two hours seems inexplicable, but the cupping is supposed to relieve by overcoming the diaphragmatic spasm by equalizing atmospheric pressure above and below.

At a meeting of the Detroit Medical and Literary Society Dr. Hitchcock reported a case of

Rupture of the Intestine.

A man working in a sawmill was violently struck in the right groin and right side of the scrotum by a board. He was seen about three hours afterward and had taken about ¼ grain of morphine to relieve his pain.

There had been vomiting, and pain referred to the end of the penis. No decisive symptoms were found; the pulse was about 88. Soothing applications were ordered.

Seen the next morning, the temperature was 97.6°; the pulse too rapid to count; an emphysematous crackling could be distinguished at the seat of injury under an uninjured skin. Rupture of the intestine was diagnosed and operated for, and the colon found torn, with its contents free in the abdomen.

The patient died shortly after removal from the table, and the case was reported to show how little disturbance might be shown by a person injured in this manner. A couple of other members recalled somewhat similar cases in which there was the same absence of prominent symptoms, or even injury of the skin, and resulting in early death.

Other papers in this issue are "External Perineal Urethrotomy," by Dr. Ernest .T Tappey; "Infantile Eczema, Especially in its Relation to the Infant's Face," by Dr. Andrew P. Riddle.

A Russian physician is recorded as having discovered that small doses of tincture of strophanthus, given about three times daily, produces a distaste for liquor in excessive users of alcohol.

IN THE BRITISH JOURNAL OF DERMATOLOGY

Dr. Wm. Anderson reports two cases of

Eruption Cheloid.

The patches of cheloid here did not extend marginally beyond their original area. Under the microscope, however, they showed the typical structure of spontaneous cheloid —the normal tissue being replaced by white fibrous bands in the dermal layer, the papillæ and rete-cones being unchanged.

In the first case the patient was a healthy-looking boy. On the knees and elbows were patches of psoriasis, on the body a number of spots ranging in size from a pin head to a three-penny piece with dull surface and a surrounding pale areola. Interspersed with these were patches with smooth, milky white skin, slightly elevated and free from hair follicles.

The patient said these appeared in spots previously to the seat of the eruption, and a spot was found in transition.

A spot was excised and found to be interlacing fibrous bands covered by papillæ and rete-cones. The marginal vessels were enlarged and surrounded by areas of unclear proliferation.

Under chrysophanic ointment the psoriasis improved rapidly, the spots improved more slowly, and later some of the cheloid spots seemed to contract and pass away spontaneously without leaving any trace.

Drawing a moistened stick of nitrate of silver around a spot caused a ring of eruption, but this disappeared.

The second case was a woman aged 26 years. The patient was tuberculous. The eruption was on the backs of the hands and disappeared under carbolic-acid ointment.

The other paper in this issue is on "Dermato-Neuroses," by Dr. St. Leloir.

BUFFALO MEDICAL AND SURGICAL JOURNAL

for November. Dr. M. Hartwig comments on the neglect of English journals to discuss the use of "ambulatory splints" in treating fractures of the lower extremities.

This treatment is being adopted in Germany and consists in the application of a splint or plaster bandage to secure apposition of the fragments, and in addition a modification of Taylor's splint for hip-joint disease, thereby supporting the body by upright splints attached to the pelvis.

Dr. Albers, of the Prussian army, combines strips of wood with a plaster bandage, obtaining the same result with a less cumbersome apparatus.

Dr. Henry L. Elsner writes of

Mixed Infection in Pulmonary Tuberculosis.

The conditions described are due to the presence at the same time of tubercle bacilli and some other infecting organism, usually the pneumococcus of Friedlander. Some of these conditions have been known for a long time, without the cause of the peculiar symptoms being recognized.

Besides the miliary form of acute tuberculosis we meet with a variety which seems broncho-pneumonic, is accompanied by hæmoptysis, and has been described as due to inspiration of bacilli, and a third which closely resembles acute pneumonia, and the green sputum frequently found in this, and which may also occur in uncomplicated pneumonia, furnished the title of a paper by Traube.

Cheesy pneumonia is not marked at the outset by the sharp chill which is usually found in simple croupous pneumonia; bron-

chial breathing appears late in the disease, sometimes the end of the second week, and instead of the characteristic subcrepitant rale we find a coarse mucous one.

Giving the theories of some other men, the author concludes that the only way of obtaining a clear diagnosis is by careful and repeated microscopic examinations of the sputa. Micrococci, streptococci and staphylococci are all found in tuberculous cases, and the significant statement is made that the injection of tuberculin renders animals susceptible to germs that had lost the power to injure healthy subjects.

The presence of this diffusible poison therefore predisposes to attacks of inflammation (pneumonia, for example).

The author classifies the cases of mixed infection clinically recognized by him as follows:

1. Cases of acute fibrinous pneumonia in which the disease attacks an area of lung tissue the greater part of which is the seat of infiltrating but latent tuberculosis. The tuberculosis here usually had origin or was coincident with disease in another organ, and usually gave no subjective symptoms until the appearance of the pneumonia.

2. Cases in which acute croupous or catarrhal pneumonia occurs near and causes changes in previously recognized tubercular areas. The pneumonia terminates by crisis or lysis and is not associated with early hæmoptysis. (*b*) Cases where the pneumonia occurs, without early hæmoptysis, in distant areas or in the other lung and the tubercular disease becomes actively progressive.

3. Streptococcus pneumonia, in which pneumonia develops from the aspiration of infecting agents from the seat of original infiltration in a case of latent or active pulmonary tuberculosis. Hæmoptysis is usually present during the stage of acute exacerbation or immediately preceding the pneumonia.

4. Cases of acute broncho-pneumonia, occasionally fibrinous, with concurrent bacillary infection, where as a result of lowered vitality there occurs rapid disorganization of lung tissue, cheesy infiltration, coagulation necrosis and death.

Analyzing his experience somewhat further, the writer gives a minute account of a case in which, about fourteen months after the emptying and healing of a tubercular ischiorectal abscess, a well-nourished man of 36 years developed pneumonia. At the outset the case seemed typical croupous pneumonia, except that it was limited to the right apex and gave absolute flatness when first seen. Microscopic examination of the sputa showed pneumococci but no bacilli. For a week the case was typical of croupous pneumonia, then a profuse perspiration sent the temperature to 99°, then it rose to 101° and tubercle bacilli could be found in the sputa. The case now showed more and more tubercular symptoms and died fifteen weeks from the outset. The author thinks tubercle bacilli can, without assistance from other disease germs, cause a pneumonia which cannot be diagnosed from croupous pneumonia expect by the aid of a microscope.

The same number contains "A Review of the Relations Between the State and the Medical Profession in New York," by Dr. Frank Whitehill Hinkle.

JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for November. Dr. Wm. Thomas Corlett writes of

Cold as an Etiological Factor in Diseases of the Skin.

A number of cases are described at length, the common features being as follows: A sudden eruption resembling herpes; the vesicles rupturing and leaving a ham-colored weeping surface, which becomes a faded rose color covered by fine scales. The eruption appears at the approach of cold weather, involves the dorsal surface of the hands or feet, disappears spontaneously at the approach of warm weather, and is not, to the author's knowledge, due to any bodily condition. Paroxysms of itching may occur, and there is a distinct tendency to return annually to the surface formerly affected.

Dr. James C. White reports a case of

Pityriasis Rubra Pilaris.

A young lady of 27 years whose skin was previously healthy noticed her palms and soles becoming red and scaly, the scalp full of dandruff, the face red and branny and papules forming. The face was a uniform dull red color and slightly scaly and thickened. The scalp was covered with a thick layer of scales, with apparently little fat. The upper part of the chest and the neck also roughened, red and infiltrated. The palms, the soles and the extensor surfaces of the fingers were greatly thickened, and the lines of flexure marked by deep and painful fissures.

Over all other parts of the body the condition was different. The mouth of almost every follicle was filled by a horny papule, varying from a pin-head to an upholsterer's tack in size. These were slightly redder than the intervening skin. For the most part this resembled no other skin affection, but where the lesions were smallest it was somewhat like keratosis pilaris. The horny papules are the distinctive features of the affection, and except for them the disease might be mistaken for seborrhœa or eczema.

Erytheme Indure des Scrofuleux.

A boy twelve years old, at first thought subject to erythema nodosum. The lesions were larger, more deeply seated, and more generally distributed over the lower limbs than usual, continued to develop for many weeks, and then many broke down, forming deep, indolent, refractory ulcers.

Another case was a girl of eighteen, with a few deeply imbedded nodules on the lateral and posterior surfaces of the legs and a few smaller ones on the arms.

Thorough syphilitic treatment was given, but many of the lesions formed indolent ulcers and the case disappeared from view. Other cases presented similar features.

At the outset these nodules were covered by seemingly normal skin and did not present the brilliant hyperæmia of erythema nodosum; also, instead of occupying the anterior surfaces, they were mainly found on the lateral and posterior parts.

The author does not recognize the right to the title indicating a tubercular origin, as he knows of no satisfactory bacteriological examination.

Lymphangioma Circumscriptum.

A man 34 years old showed the following: The left lateral thorax from the axilla to the last rib and from the nipple to the anterior margin of the scapula was occupied by—

1. Groups of prominent vesicles varying in size from the head of a pin to a small pea, with very thick and firm epidermal coverings. The contents were colorless, or dirty yellowish, and of rather thick consistence. On the borders the vesicles formed small and sparse groups, but in the central portion were densely crowded. By rupture they were converted into oozing areas.

2. Large elevated crusts, thick and of fi m consistence, yellow or reddish in color, formed apparently by coagulation of the contents of the vesicles. Some of them were two or three inches in diameter.

3. Crimson elevations of pea size, resembling angiomatous new growths of cock's-comb character. They were firm, became slightly paler on prolonged pressure, and were sparsely interspersed among the vesicles.

4. Verrucous nodular masses of considerable size and height, some of them capped by dense horny concretions.

The whole upper arm presented on its inner surface similar but more pronounced lesions.

Microscopic examination of a lesion showed lymph vessels connecting with cavities consisting of dilated lymph vessels or spaces of similar formation. The author favors the opinion that these were of new formation and not dilated vessels simply. There was no true elephantiasis.

Multiple Benign Cystic Epithelioma.

This case is reported because the adjective benign seems misplaced, and it leads to the question whether these cases do not all tend toward malignancy.

The patient is a woman of 45 years, the mother of eleven children, only three surviving. No member of her family suffers from any skin eruption.

At the age of twenty-four a few firm pimples appeared scattered over her face, and others kept growing until three years ago. Ten years ago some underwent softening and were removed with caustic preparations, leaving only flat scars. About fifty lesions are to be found over the face, varying from small flat, almost invisible tubercles, larger reddish lesions, one of which is the size of a quarter dollar, to two or three much more prominent, presenting abrupt edges with depressed centers resembling Hutchinson's crateriform epitheliomata and measuring from one-half to three-quarters of an inch in long diameter.

The right upper eyelid is the seat of a rodent ulcer, closing the eye.

Sections from some of the lesions showed, microscopically, masses of epithelial cells, and often showed direct connection between these and the lower rete layers. These cells were often found to surround small cysts containing sometimes a corneous substance, sometimes cells undergoing colloid change.

Dr. John P. Bryson writes of

The Question of Surgical Interference in Tuberculous Kidney.

In the author's experience when a case presents itself there is invariably infection also of the lower urinary passages, and usually of the seminal vesicles and the prostate, before there appears to be excuse for surgical interference.

"When in kidney colic," the author says, "the pain shoots quickly into the testis and causes its marked retraction the cause is situated low down in the ureter; but the cause of the trouble is up toward the kidney or in that organ when, in the absence of this set of symptoms, the pain quickly passes to the opposite side and causes nausea and vomiting."

The author thinks that so many points are to be taken into consideration in every case that no generalized rules can be laid down for operation in these cases.

He is decidedly opposed to interference, when avoidable, for fear of rendering a chronic inflammation acute. To relieve fever and suppuration by incision and drainage or the removal of a stone is an imperative duty, but to attempt to cure a latent disease by operation is useless.

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM NOVEMBER 25, 1894, TO DECEMBER 1, 1894.

The extension of leave of absence on surgeon's certificate of disability granted First Lieutenant Henry R. Stiles, Assistant Surgeon, is further extended two months on account of sickness.

Leave of absence for one month, to take effect on or about December 10, 1894, is granted First Lieutenant Charles Lynch, Assistant Surgeon, with permission to apply for an extension of one month.

NEWS AND MISCELLANY.

Important to Commercial Travelers.

On and after December 1st, Baggage Agents of the B. & O. R. R. Co. will accept coupons from mileage books issued by B. & O. R. R., P. & W. R'y, B. & O. S. W. R'y and Valley R'y of Ohio, in payment for excess baggage charges, at their face value, 2 cents each. This arrangement will not include B. & O. Mileage Books indorsed "good only on B. & O.," B. & O. Southwestern Mileage Advertising Books, nor books older than one year from date of issue.—2t

ORIGINAL ARTICLES.

PUZZLING POINTS IN LABOR.*

GEORGE R. DEAN, M.D., Spartanburg, S. C.

The environments of a patient in labor, the available help at hand and the outlook for after-treatment are modifying influences which no surgeon or general practitioner can ignore. Many complications in labor which the accoucheur is at any time liable to encounter must be met and treated promptly. Often they occur in regions remote from skilled assistance and where it is almost impossible to obtain needed surgical supplies at the time. Such emergency cases, arising under varying conditions and circumstances, have suggested a title for this paper. I have had much experience in cases where the conditions were such that delay would seriously endanger the life of the mother, and it was not a question of ideal surgery, but what could be done to save the patient.

A few years ago craniotomy was thought to be the sole operation that offered a thoroughfare out of the difficulties that the forceps could not relieve. This, to a certain extent, has been superseded of late years by operations which, under certain conditions, promise more to the child, if somewhat less to the mother. Craniotomy is a cruel operation. It takes the life away from one totally helpless and without a voice in its own destruction. The doctor becomes judge, jury and executioner. Under certain conditions it is still the right and proper thing to do. But with the advancement in surgery, wrought by a keener conception of the principles which underlie and develop its wonderful success, the conditions demanding this terrible operation are diminishing year by year. Recently a distinguished member of this association went so far as to contend that under no conditions should craniotomy be performed upon a living child. While I cannot fully subscribe to this opinion, I believe the conditions necessitating its performance are daily diminishing. The success obtained by Sanger's operation and by Porro's, and lately the good resulting from symphyseotomy, have caused these to be substituted in many cases for this more barbarous procedure. And yet there are cases where craniotomy would offer the best chances of success—all things considered.

The brilliant successes obtained in operations performed for the purpose of saving the child have mostly been upon subjects whose conditions have been previously understood thoroughly, and when every preparation has been made for the anticipated work. Many of the cases thus treated had formerly undergone craniotomy; or at any rate the deformities and other impediments to natural delivery had been well known. Results under such conditions cannot be taken as those which we should expect from cases with which physician is suddenly confronted, of which he has had no previous knowledge and for which he has made no special preparations.

All must admit that to do a "Porro,"

* Read before the Southern Surgical and Gynecological Association, November 14, 1894.

a "Sanger," or even a symphyseotomy, one must assume a great responsibility and take upon himself much labor and anxiety. Only those physicians who live in remote districts and in the smaller towns, where the dread of the knife overshadows all things else with patient and friends, can realize with what temerity an operation is mentioned. It is far different in large cities and in more intelligent communities. There the surgeon would be sustained and commended in his heroic efforts to save both mother and child. The mortality of these procedures under the most favorable circumstances is such that no man should undertake them without thoroughly going over all the ground.

Symphyseotomy is not such an extensive operation as the Cæsarean section, nor is it fraught with so much risk. Still it is a serious one, and may lead to trouble if not done carefully and followed with proper after-treatment.

What, then, are the indications which should guide us in selecting the operation best suited to each individual case? Before attempting to answer this, I wish to refer to conditions incident to location and surroundings. In the Southern States we have a large negro population—a race inured to the poorest and most beggarly environments in their home life. Among these the physician is often confronted by obstacles to delivery which require some one of these operations. As an example of what may be met with in this class at any time and in any community, I cite the following case:

I was called in consultation to a poor colored woman in labor, a primipara upon whom the forceps had been used unsuccessfully for four hours. Her bed was a mass of filthy rags, as was also her clothing; the house small, open and dirty—squalor and filth were visible everywhere. Dusty cobwebs that had not been disturbed for years hung in festoons upon the walls. One small room, 12x14, contained two beds and was occupied by four people. Such were some of the surroundings. Fortunately by turning I succeeded in delivering the child, and thus was spared a more serious operation. But suppose I had not been successful in this: what measures could I have taken in its stead? What would have been her chances for recovery under a Cæsarean section, or even a symphyseotomy? Had I been forced to any other method, I would certainly have chosen craniotomy, believing that with care and patience I could have safely gone through that performance and left my patient in a fair way to recovery; whereas with either one of the others the outlook would have been entirely different.

This is a fair sample of conditions which indicate that craniotomy would offer the safest means for the patient at our command. A decision must be arrived at in such cases after a careful, conscientious and intelligent investigation of everything that concerns the situation. If the impediments to natural delivery in any given case are known to the physician before the end of the term of gestation, thus giving him time and opportunity to make all necessary preparations, the selection of the operation promising the best result is not difficult. Here accurate measurements of the birth channel can be taken and arrangements for nursing and after-treatment can be thoroughly provided; the physician at a moment's notice is ready and prepared to carry out his formulated plans. But in cases where conditions are not known to the physician and he is suddenly confronted by obstacles to delivery which cannot be overcome except by some one of these operations, this decision is not so easily arrived at. The physical condition of the patient, the amount of exhaustion present, the environments, the availability of intelligent assistance and the outlook for proper after-treatment are factors which must have bearings of the greatest moment in reaching an intelligent decision.

The country physician, far removed from educational centers, cannot possibly arrive at the same conclusions in such a case as can his more fortunately situated city brother. With no less fortitude and regard for the life of the child and the well-being of the mother, but with his limited paraphernalia, he could not hope to do a Cæsarean section or a symphyseotomy with any prospect of success, save under the rarest circumstances; whereas the city physician or the specialist, equipped with all that is necessary for such work, familiar with all its details and able to procure the best assistance at a moment's notice, can safely arrive at a very different conclusion. Where, therefore, a craniotomy would be proper in the former case, one of the other operations would be

equally proper in the latter. The conclusion is that in every case that operation must be selected which promises the best results, *all things* considered.

The term Cæsarean section as herein used is to be construed in a general sense, including either a "Sanger" or a "Porro."

When operations of any character are found to be necessary for the delivery of a child, dead or alive, they should be performed as early in the case as possible, sparing the woman's powers and thereby adding to the chances of success. If mother and child are to have the best prospects of being saved, operations must not be postponed until the patient has become exhausted. There can be no excuse, and there certainly is no reason, for permitting a woman to suffer hour after hour without progress, putting forth all of her strength in useless endeavor to overcome the impossible until that exhaustion supervenes from which nothing can save her.

The points I wish to emphasize are: First, the saving of both mother and child where possible is the end to be attained above all other considerations. Second, to accomplish this everything pertaining to the situation or surroundings, and the physical condition of the patient should be carefully considered. Third, wherever the impediments to delivery, from whatever cause, are too great to be overcome by the forceps or by turning, the surroundings and condition of the patient permitting, symphyseotomy offers the best results with the least traumatism to the mother. Where this is impracticable from any cause, the surroundings and condition of the patient permitting, then the "Sanger" or "Porro" operation should be performed. Where neither of these operations is practicable in consequence of conditions or surroundings, then, and only then, should craniotomy be performed.

These are the conclusions at which I have arrived: First, craniotomy should never be performed under any circumstances where it can be avoided with a reasonable hope, *all things considered,* of saving both mother and child by some other operation, even though it be a serious one involving very great risk to both mother and child.

Second, there are cases where craniotomy promises the only reasonable hope of saving the mother.

Only a close observer and a conscientious physician, alive to all the hopes of a joyous motherhood and with an honest desire to do his duty to God and his fellow-man, can be capable of judging as between mother and child when one must be sacrificed for the safety of the other.

I have done craniotomy and may have to encounter its horrors again, but it will be performed by me only as the last resort.

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., NEW YORK.

[CONTINUED FROM PAGE 787.]

ETIOLOGY.

There exists some divergence of opinion on the causative factors in bruises of the abdomen. Extensive studies have been pursued to elucidate this feature of the subject, yet much remains unsettled.

The most complete and the only methodical series of experiments ever conducted in this country on the lower animal, with a view of elucidating the subject of abdominal contusions, known to me, was published by Dr. B. Farquhar Curtis (*American Journal of Medical Sciences*, October, 1887).

These experiments were further amplified by others on five or six cadavers. Forty-four dogs were experimented on, contusive force alone being employed in all. The abdomens were traumatized by allowing pieces of wood and iron to fall on them, the animals being etherized. In ten no serious harm followed. In only eight was the intestine ruptured. None were immediately killed by the blows.

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

The author's observations on the cadaver showed that the jejunum and upper part of the ilium were most exposed, and that when one of the hollow organs was ruptured it was caused by being crushed against the spinal column. In 116 collected cases by this author most were injured by kicks and run-overs; but four were buffer injuries. Areas of the intestinal canal were involved in 113 cases; the duodenum, 10; jejunum, 44; ilium, 38; other parts of small intestine, 21; colon, 4. Shock was present in 80 per cent.; severe pain in 104 cases.

Early in the spring of 1879 Professor Giornardi, of Genoa, made an extended series of similar observations and experiments on the lower animals for the purpose of endeavoring the more precisely to determine the causative factors in injuries of the abdomen ("Effets de Coup Violent sur l'Abdomen," *Gaz. des Hôpitaux*, May, 1879). As a result of his remarkable experiments, of which space will not permit a detailed account, he summarizes briefly as follows:

"1st. When such a degree of violence is applied over the abdominal wall as will lead to intestinal rupture, the mucous and muscular layers are the first to give way and the fibro-serous last.

"2d. This being the case, rupture of the inner coats with hemorrhage into the bowel does often occur when the peritoneal investment has preserved the continuity of the lumen, prevented extravasation and favored repair.

"3d. When the bowel has suffered very serious damage, though there may be no immediate rupture, perforation may occur through a gangrenous patch any time from five to ten days or later.

"4th. Mechanical rupture of the intestine, complete or incomplete, either alone or in conjunction with laceration of the solid viscera, follows not from *contre-coup* reflected force, but by direct impact against the vertebral bodies."

Moty divides abdominal contusions into three classes, based largely on their etiological elements (*Revue de Chirurgie*, No. 11, 1890). The author sums up with a warning not to be too premature with a favorable prognosis, in view of possible complications which may subsequently unexpectedly arise.

Prof. Charles McBurney (*New York Medical Journal*, January 26, 1889) reports a highly interesting case of a boy who fell on his abdomen, striking a rail on a railroad. Shock was very marked; he was injured at 3 P.M. McBurney and the consulting staff decided to operate at 11 P.M., intestinal perforation being suspected. Found abdomen full of blood, with laceration of the gastro-duodenal artery. Intestine not injured. The patient recovered.

It would seem remarkable that a fall, or rather stumble, could cause such a rupture of the vascular structure. The majority of abdominal injuries are caused, not by contusion by blows, but by compression, as in run-over cases, the abdomen being crushed violently between two hard resisting bodies, as under wheels between two cars, the so-called "buffer injuries," being caught under falling bodies, etc.

In conjunction with the abdominal injury in this class, we will often meet with associate fracture of bone as a complicating element. In this class, as in contusions, the weight of testimony is that in the vast majority of cases the abdominal contents are lacerated, not by concussion or percussion, but by the intestine or other organ being driven back or downward with great force against the vertebral column or the pelvic ridge.

DIAGNOSIS.

The diagnosis of intra-abdominal traumatisms, as of lesions of a pathological order, is generally attended with very many difficulties. In no case is there any reliable and safe means known by which it is possible either to detect or locate complete rupture of any part of the alimentary canal within the abdomen.

Even if there were a definite symptomatology, in many instances it would avail us nothing, for it is to be remembered that the tendency of an injured intestine is to take on immediate spontaneous adhesive inflammation, and thus effect a cure without interference; spontaneous union here being remarkably and singularly efficient as a salutary process when not disturbed. Besides, in many general shock is very great and impending collapse so threatening that radical measures may and often do deprive our patient of his only hope of recovery.

In the near past it was heralded far and wide that an exploratory abdominal incision under aseptic or antiseptic precautions was harmless. But time has proven that

this was both a dangerous and a fallacious assumption, and that no means known to art will in any manner whatsoever obviate the dangers inherent in an abdominal section made while a patient is under shock.

Stimpson's statistics have demonstrated conclusively that in gunshot penetrating wounds of the abdomen the mortality was largest when active intervention was adopted. Réclus and Berger's observations ("Penetrating Gunshot Wounds of Abdomen," *New York Med. Jour.*, January, 1889) were in the same direction.

Bryant gives the records of 74 severe non-penetrating injuries of the abdomen admitted into Guy's Hospital in eight years. In 44, beyond a passing collapse they rapidly recovered and no bad symptoms followed. Three had peritonitis of an acute type, one terminating mortally. In 17 it was believed that rupture of the viscera took place. The author cited the case of a man among the group who, in a fracas with a woman, was hit violently over the stomach. He immediately collapsed. He quickly rallied and went around for a week, when acute peritonitis followed, from which he ultimately recovered (*British Med.. Jour.*, May 12, 1892).

Morton collected 234 cases of abdominal bruises, in which he found that the digestive tube was injured about once in eleven cases, or in less than 10 per cent. (*N. Y. Medical Record*, July 6, 1889). Jalugeries' tables comprise 345 cases of intestinal rupture. The stomach was ruptured but once. In their order of frequency of rupture the small intestine came first and the various segments of the colon next ("Contusion de l'Abdomen," *Bulletins et Mem. de la Soc. de Chir. de Paris*, April, 1893).

Michaux (*ibid.*) cites three grave cases of abdominal contusion. One refused laparotomy and died; the other two submitted. Internal perforation was found in both. Recovery followed in each.

This author dwells at length on the difficulties in diagnosis. He would advise delay in all cases of shock.

When in doubt he would not operate. Exploratory incision for diagnosis he disfavors, but where reaction sets in and septic peritonitis is formed he would promptly laparotomize. Tillaux, in a valuable contribution on these injuries, observes that at the time of accident exact diagnosis is extremely difficult, on account of shock which may be dependent on causes quite independent of the abdomen and various pathological conditions within it.

"The aspect of the abdominal walls," he truly says, "furnishes us with no definite knowledge of the pathological condition within the cavity." A man was brought into his service who had been injured over the abdomen. There were no surface indications of traumatism. He died in shock. On autopsy it was found that the greater part of the mesentery was torn off and a vast hemorrhage had accumulated. After shock passes away he says that "the facial expression independent of the temperature is quite pathognomonic of peritonitis" (*Gaz. des Hôpitaux*, October 7, 1886). From the preceding observations it is obvious that symptomatology is anything but clear in these lesions. It is important, however, that when it is possible a definite diagnosis should be made, and as soon after injury as is practicable.

PATHOLOGICAL ANATOMY.

The immediate sequelæ of an abdominal injury which threaten life are—

1st. Hemorrhage.

2d. Intestinal rupture.

3d. Peritonitis.

Hemorrhage within the peritoneum in some respects is not unlike that into any other serous cavity. Bleeding within the skull, the pericardium or the pleura imperils life, not by its loss so much as its mechanical effects, irritation, etc.

But within the peritoneal cavity, as its walls are distensible and its contents movable, this does not obtain. The loss of blood in this cavity may be quickly fatal through its volume alone. Intra-peritoneal hemorrhage is no doubt more common in abdominal traumatism than is generally supposed. In moderate quantities no serious harm follows. But when a solid organ is cut or a large vessel opened, the escape may be large and the consequence serious.

In most cases, when the loss of blood is great we may determine its presence by physical signs as well as through the general symptoms. Its most striking clinical characteristic is the great prostration of the vital powers.

In shock from intestinal rupture great pain is superadded. In hemorrhage, too, thirst is urgent and nausea is wanting. The amount of hemorrhage will depend on the structure opened.

Mr. J. T. Taylor (*Lancet*, May 7, 1883) gives the history of a boy who sustained a blow on the abdomen, dying in syncope almost immediately after. On autopsy the aorta was found ruptured just above the bifurcation into the common iliacs. But the vascular structures may suffer serious damage in these cases without the lose of blood, as is proven by Malgaigne's case of a man who had sustained a violent blow over the hypogastrium.

As this man recovered from shock and began to regain his strength, symmetrical gangrene commenced in his lower extremities and he soon died. Post mortem: the abdominal aorta was found occluded by a massive clot and both of its inner coats ruptured (*Bull. de l'Academie de Med.*, June, 1863).

Hemorrhage into the peritoneal cavity will gravitate, but that of a renal origin will lodge in the retro-peritoneal tissue of the flank and hypogastrium, though in some the leak is into the pelvis and out through the urine. There is no distinctive symptom which will always definitely indicate what organ or tissue intra-peritoneal hemorrhage is derived from, hence our hypothesis must rest on an *ensemble* or aggregation of symptoms rather than any single one.

Since the recent era of revival of intestinal surgery and since, under the new *régime* of antiseptic therapy, several enthusiastic investigators have insisted with great emphasis that the early precognition of intra-peritoneal hemorrhage is of prime importance, in order that its source may be sought out and effective hæmostasis instituted.

But time has demonstrated what has been well known for ages, viz., that intra-peritoneal effusions of blood are rapidly disintegrated by the lymph and that the serous membrane resorbs it with great rapidity. We have further learned from observation on the human body that when a structure is lacerated, as the portal vein, the vena cava or aorta, little can be accomplished by an abdominal section.

Intestinal perforation or rupture may occur as a primary lesion after severe injury of the abdomen or consecutively. The detection of an intestinal rupture by any series of symptoms immediately after injury is quite out of the question, though the presence of great pain is strongly presumptive of it.

It may be suspected, too, when shock deepens with agonizing distress, when the eyes are sunk and the features are pinched. But more than once have mortal cases of perforation been witnessed by myself when there was little or practically no shock; and, on the other hand, in not a few the most profound shock and subsequent acute peritonitis has been observed, but no mortal perforation followed.

As a general rule, however, the persistence of violent pain with great depression and nausea is a fairly reliable indication of intestinal rupture.

Inflating the alimentary canal from either above or below may perhaps aid in deciding diagnosis, but it must be regarded as an expedient attended by more danger than counterbalances the additional knowledge it may convey.

It remains a question thus far whether we should be contented to wait when we are in doubt until reaction sets in and symptoms are better accentuated or press for an exploratory incision. It goes without saying that when such an incision is made, preparation for simultaneous treatment of the rupture in the bowel, if one is found, should be complete.

But it is a procedure of so much difficulty and gravity that it should not be undertaken without deliberation, and never by any one other than an experienced surgeon if such can be had, for sometimes the point of leakage, though easily recognized, is situated in such a part that operative treatment of it is quite impossible in any but experienced hands.

Peritonitis of a traumatic type follows (1) from contusion alone, (2) from hemorrhage, (3) from leakage of the gland ducts or the alimentary canal.

Parietal peritonitis is eccentric or centric; in the former irritation being conveyed inward by the lymphatic vessels from peripheral injuries. This variety is as common as it is generally harmless. It is always associated with a peripheral cellulitis. It is not painful unless the body is moved or when the diaphragm is suddenly contracted. It may be local or general. No paresis of the viscera occurs in this form unless the hypogastrium is the

seat of inflammation, as when the reflexion of peritoneum over the fundus of the bladder is involved vesical paresis and retention of the urine supervene.

Central, or perhap what should be more properly designated *visceral*, peritonitis is altogether a more serious affair and is usually ushered in by a set of symptoms of moderate severity. Such is that which follows the irritation of a large hemorrhage, a moderate bruising of the intestine or fixed viscera, slight leakage of gases or fluids from the intestine, the various ducts, the gall or urinary bladder.

When the peritoneum is inflamed one of the most unvarying symptoms is arrest of peristalsis and enteric paralysis. The patient is constipated and perhaps incessantly vomits. Besides, he has the usual syndrome of fever. The pain of peritonitis is generally of a most agonizing character and is not apt to be mistaken for anything else. Along with these symptoms are the cadaverous features, the painful suspense and mental anguish.

It may be said that peritonitis of various types is an invariable concomitant of all grave abdominal injuries which run into the stage of reaction.

RUPTURE OF THE BLADDER.

When the bladder is distended it rises into the abdominal cavity, pushing the intestines upward and backward. When thus filled it lies close to the abdominal walls and is exposed to rupture by violence, though the healthy organ possesses remarkable resisting qualities to injury even when greatly distended.

It is quite possible that diminutive rents in its walls occur more commonly than we suppose, but that, owing to its own innate tendency to spontaneous repair and the facility with which the peritoneum will absorb aseptic urine, we do not discover them.

Several cases have come into my hospital service for operation which had been diagnosed as bladder rupture. The patient had been crushed or run over some time before. Not being able to urinate, a practitioner being called would possibly introduce a gum-elastic catheter.

He would find that this would go in a great distance, but no urine would flow, and hence the patient would be hurried off to hospital for laparotomy.

On entrance, a careful external examination would reveal a vast zone of dullness which could be marked off over the hypogastrium. A large catheter would be introduced and a suction applied to withdraw the blood-clots. From one to three pints of urine might be withdrawn and that would be the end of the trouble. In another class of mistaken cases in men after injury over the lower abdomen they will complain of great pain in the bladder. Now, if one is not cautious he may again diagnose rupture, though the bladder this time is empty and patulous. A hard catheter will be passed in and its tip may be felt anywhere over the hypogastrium as far up as the umbilicus.

I was notified about a year ago that such a case was in the hospital in need of urgent laparotomy for rupture. By telephone I directed that the bladder should be distended with six ounces of sterilized water, which was then to be withdrawn. This was done, all the water coming back as it entered, unchanged, in the same exact quantity. This is a simple and accurate test when one is in doubt. What causes the deception in these latter cases is the elastic wall of the bladder receding away before the top of the catheter.

In those cases of strongly suspected vesical rupture a positive diagnosis may be made for intra-peritoneal perforation, but the general peritoneal cavity must be opened to reach the seat of injury. To open this under a mistaken diagnosis might cost the patient his life and possibly involve the operator in very serious legal proceedings.

Treatment.—"In the treatment of this class of cases," says Hodgen, "no general line can be laid down, no canon can dictate our course" (Hodgen on "Abdominal Contusion," Holmes' "System of Surgery," vol. xi, p. 491).

As the greater number of cases of abdominal bruises present no serious features, they should be treated on general principles.

Rest occupies a place of prime importance. Our patient should be placed in such a position as affords the greatest comfort. Nature itself enforces this decree. The strained, lacerated and contused muscles of the abdomen refuse to act without a protest, for the least movement of them gives excruciating distress. The activity of all the functions of the economy is sensibly diminished. Breathing is shallow.

The heart's stroke may be increased in frequency, but its impulse is weakened. Secretion and excretion reduce their output, the appetite temporarily fails, the injured patient seeks undisturbed quiet; the plain and emphatic admonition, then, is *rest.*

Protracted manipulation and the institution of tedious diagnostic tests may add much to the patient's sufferings and are prolific sources of augmented distress.

If our patient is not in shock, but suffers pain and is not very weak, our relief measures will be simple. If pain is but moderate and peripheral, local applications will give relief and in a few days our patient will be up again.

In another class, in which the degree of injury is greater and shock is present, the same principles will apply, but as there generally is great depression and severe pain here, stimulants and sedatives are demanded. Heat to the extremities, with alcoholics and opiates, are now called for.

When alcoholics can be borne they are of infinite value judiciously administered.

They exhilarate the drooping spirits, reduce pain and favor sleep. In cases of severe abdominal pain morphine must be conjoined and freely administered; but we must be cautious not to narcotize and in this manner destroy the life we are endeavoring to save.

A broad binder over the abdomen in some cases gives great comfort, but where there is a tendency to tympanites the belly must not be encumbered by any description of compress. It is highly important to bear this in mind in male cases, for with them respiration is largely diaphragmatic. Hot or cold applications over the abdomen, according to which gives the most comfort, should be applied.

The Use of Mercury.—My own experience has convinced me that mercury freely administered early after an abdominal traumatism exercises most potent properties in preventing or greatly modifying inflammatory processes in the serous membranes. In these cases it should be employed by *inunction* and continued until the gums are touched or the danger of general peritonitis is past.

Surgical Interference.—But what shall be done in those grave cases in which we are reasonably assured that there is a large hemorrhage or rupture of the bowel?

As heretofore stated, the general opinion now is that one should not laparotomize during shock. There are aggressive young surgeons who would allow almost nothing to stay their hand were they only certain of intestinal rupture.

We may gather an impression of the extremes in this direction from the following paragraph by Dr. J. D. S. Davis, of Birmingham, Ala. ("Medico-Legal Aspects of Intestinal Surgery," Boston *Medical and Surgical Journal*, January 28, 1892): "There are those who condemn all mechanical aids for intestinal repair; know not how to use them, never saw them used, refuse to indorse a resection for a gunshot or stab wound, and are known to go on the stand for purposes of condemnation and disproval when they know no more about intestinal surgery than a wild Indian about school-teaching."

Contemporaneous surgical literature chronicles some few successful cases laparotomized for rupture of the intestine following contusion of the abdomen. The worst of it is that some surgeons who have had bad results are often swayed by motives of expediency and policy not to publish all their failures; hence no reliable table of statistics can be had.

Michaux lays down rules for our guidance based on his own extensive experience and supported by such rational deductions that it has seemed to me they may be, in part at least, adopted here as our safest guide when we are called in to treat this class of cases.

"Interfere at once," he says, "when there are unequivocal symptoms of perforation or large internal hemorrhage, for however deplorable such intervention may be, it is our patient's only hope."

He most judiciously insists, however, that in the vast majority of abdominal injuries the internal organs escape, though immediately after injury it may be difficult to distinguish the milder from the more grave type.

For this reason, in the average case he recommends delay until symptoms of peritonitis appear, when the indications for interference are formal.

[TO BE CONTINUED.]

MY son, if a person calls you an ass, do not kick. That would only serve to corroborate his assertion.—*Boston Transcript.*

DR. OLIVER WENDELL HOLMES.*

GEORGE T. WELCH, M.D., PASSAIC, N. J.

The death of this veteran physician, poet and literary genius will give rise to a host of valuable recollections and comments from all who knew this or that side of his varied character. For in his old age, like a genial, sparkling flame on a winter's hearth, he has shed cheer and revivified the emotions of all who have come within his influence. But while others praise his debonnair philosophy, his inexhaustible good humor, his sparkling muse, I would chiefly recall his value to us and to humanity as a physician.

While so much is still nebulous in our great art—the greatest of all arts, for it deals with life itself—yet fifty years ago medical men dealt with obscurities that we can scarcely comprehend, so far upward have we struggled out of the mists that confused our fathers. Few great principles have sprung fully developed into the intellectual world but first existed as surmises, at length as theories that stood on no very certain foundation, and finally under the observation and experiment of widely dissevered minds the truth has been established. The germ theory of disease is a notable instance in point. You can scarcely open the pages of an author of note writing during the past two or three hundred years or so but you will find allusions to something in the air fomenting and aggravating certain diseases. As time went on the doctrine was accepted like the Scotch verdict—unproven but believed. While in our own memory it has been investigated by many scientific men and demonstrated beyond cavil by Tyndall and numerous microscopists here and abroad.

The contagiousness of puerperal fever had been asserted here and there during the last century, Gordon in 1795 saying: "I arrived at that certainty in the matter that I could venture to foretell what women would be affected with the disease upon hearing by what midwife they were delivered," but the fact of the contagion was denied more than fifty years afterward by such men as Hodge and Meigs in America. Dr. O. W. Holmes in 1843 published his affirmative observations as to the fact of its contagiousness and was assailed with virulence by Meigs for the position he had assumed. Hodge was more courteous, but none the less an opponent. "You can never convey," says he in 1852, "in any possible manner, a horrible virus, so destructive in its effects and so mysterious in its operations as that attributed to puerperal fever." Meigs followed, in 1854, in his more prejudiced and rancorous manner. He attacked Holmes with much bitterness, and assured the students who attended his lectures and the public that read his books that "in the propagation of puerperal fever they could have no more to do than with the propagation of cholera from Jessur to San Francisco and from Mauritius to St. Petersburg;" but the irresistible array of evidence and the conclusions derived from them, marshaled by the indomitable Holmes, forever put the question at rest in America and helped to mold opinion on the continent. Whoever has read Holmes' masterly essay on this topic must have felt the force of his original genius and his rich good nature, even if he had never read a line of any other of his works. His keen, good-humored satire cut Meigs to the bone and set our fathers laughing, and he who has laughter on his side does not need to blow one blast on Roderic's hunting horn to summon a thousand men.

Meigs in his diatribe made an appeal to his students, calling them "dear young friends," "dear young gentlemen," and seeking to poison them against Holmes by specious reasoning and appeals to their affections. Holmes retorted that the "dear young gentlemen" might know what to expect, from his own case, if they happened not to think as their master did. "You have naturally faith in your instructors," wrote Holmes, "turning to them for truth and taking what they may choose to give you; babes in knowledge, not yet able to tell the breast from the bottle, pumping away for the milk of truth at all that offers, were it nothing better than a professor's shriveled forefinger."

* Read before the Passaic City Medical Society, November 14, 1894.

Holmes did an immense service to the profession and to the public at large in his "Homœopathy and Its Kindred Delusions." The former has long since trenched upon our rational system of medicine to that degree that it has lost its distinctive character, and having become a greater fraud than ever before, trading as it does under false colors, it only keeps up its semblance by appealing to a sentiment, and may be very well dismissed from further consideration here.

But it was in his essays on "Currents and Counter-Currents in Medical Science" and "Border Lines of Knowledge in Some Provinces of Medical Science" that Dr. Holmes endeared himself to the progressive minds in medicine. It was here that this genial teacher dealt such trenchant but withal happy blows at the heroic treatment of his time. With the exception of Forbes in England and Bigelow in America he was almost alone in this manful strife, and for a time his fearless utterances alienated the friends of his life; but his was not one of those politic cowardly souls that bend with the current, but like another Hercules he bent the current his way and lived to see his views established in the practice of our later time, though God wot there is enough delusion even now.

"Much," said Holmes in his "Border Lines," "which is now very commonly considered to be the result of experience will be recognized in the next or in some succeeding generation as no such result at all, but as a foregone conclusion based on some prevalent belief or fashion of the time."

"There are, of course," said he, "those who go about the work of the day, doing it according to the rules of their craft and asking no questions of the past or of the future, or of the aim and end to which their special labor is contributing. These often consider and call themselves *practical men.* They pull the oars of society and have no leisure to watch the currents running that way; let theorists or philosophers attend to them. In the mean time, however, these currents are carrying the practical men, too, and all their work may be thrown away, and worse than thrown away, if they do not take knowledge of them and get out of the wrong ones and into the right ones as soon as they may. Sir Edward Parry and his party were going straight toward the pole in one of their arctic expeditions, traveling at the rate of ten miles a day. But the ice over which they traveled was drifting straight toward the equator at the rate of *twelve miles a day,* and yet no man among them would have known that he was traveling two miles a day backward unless he had lifted his eyes from the track in which he was plodding."

Ever since Bigelow, in 1835, delivered his celebrated discourse on self-limited diseases, a gradual change began to work in the practice of our profession. It was seen that many diseases must leave the system of the sick man because of a great law of nature and not because of the drugs that he may have swallowed. Indeed, it is no secret that many get well in spite of the drugs that have mistakenly been pressed upon them. The tremendous chemic force of the body has wrestled with the poisons that have been stupidly administered, changing them in character, rendering them innoxious, and where this was impossible has eliminated them at the same time that it was wrestling with a deadly disease and holding it at bay until the laws of its own nature destroyed it at the appointed time. The knowledge of this principle caused Holmes to exclaim: "I will venture to say this, that if every specific were to fail utterly, if the cinchona trees all died out, and the arsenic mines were exhausted, and the sulphur regions were burned up, if every drug from the vegetable, animal and mineral kingdom were to disappear from the market, a body of enlightened men, organized as a distinct profession, would be required just as much as now, whose province should be to guard against the causes of disease, to eliminate them if possible when still present, to order all the conditions of the patient so as to favor the efforts of the system to right itself, and to give those predictions of the course of the disease which only experience can warrant. Great as the loss would be if certain active remedies could no longer be obtained, it would leave the medical profession the most essential part of its duties and more than its present share of honors; for it would be the death-blow to charlatanism, which depends for its success almost entirely upon drugs, or at least on a nomenclature that suggests them."

Some of Holmes' aphorisms are more pointed than any others written by medical philosophers.

"The best proof," says he, "that the community is overdosed is that no families take so little medicine as those of doctors, except those of apothecaries." He bluntly asserts that when talking of their treatment doctors count only their favorable cases, and tells that old story of Lord Bacon's of the gifts of shipwrecked people hung up in the temple, "Behold! they vowed these gifts to the altar, and the gods saved them. 'Ay,' said a doubting bystander, 'but how many made vows and were shipwrecked notwithstanding?'"

"One of the most ancient of superstitions is that disease is a malignant agency or entity, to be driven out of the body by offensive substances, as the smoke of the fish's heart and liver drove the devil out of Tobit's bridal chamber."

He quotes Pliny as saying that "the cerates and cataplasms, plasters and collyria and antidotes," abundant in his time, as in more recent days, "were mere tricks to make money."

Of the self-complacency of the physician who announces that he has discovered a remedy or a system that has conquered or will conquer a certain deadly disease from this time on, Dr. Holmes alludes to the attitude of Benjamin Rush in 1799, when he believed that he had mastered yellow fever. "Thank God!" cried Rush, "out of one hundred patients whom I have visited or prescribed for this day I have lost none." "Where," exclaims Holmes, "was all this legacy of knowledge when Norfolk was decimated? Where was it when the blue flies were buzzing over the coffins of the unburied dead piled up in the cemetery of New Orleans at the edge of the huge trenches yawning to receive them?"

In speaking of the sublime effects of fresh air and proper sanitation, he tells how Dr. John Clark by a simple measure of ventilation saved more than sixteen thousand children's lives in a single hospital, and pointedly asks, "How long would it have taken small doses of calomel and rhubarb to save as many children?"

In reverting to that old Spartan rule of exterminating the hopelessly sick children of the tribe, he stoutly asserts that "hydrocephalus, tabes mesenterica and other similar maladies are natural agencies which cut off the children of races that are sinking below the decent minimum which nature has established as the condition of viability before they reach the age of reproduction. They are not so much diseases as manifestations of congenital incapacity for life."

When I set out to write this short essay I thought to compile many of Holmes' wise and witty sayings, but looking into his book was like looking into Macbeth's glass, where the long line of kings stretched out indefinitely, for where I saw one fine passage twenty others were on their feet and clamoring to catch the speaker's eye, so that I have been obliged after all to give a meager showing. But I would advise any one who has not dipped into that treasury to read his "Medical Essays" at once. It is a virile book and will beget thought in a man's head.

Quite Libelous.

A young woman from Baltimore who had been in the Far West was telling a New Yorker about it.

"And away out in the mountains I met such an educated Chicago man," she was saying in the impetuous way of a Baltimore girl.

"A what?" asked the New Yorker in astonishment.

"An educated Chicago man away out in the mountains," she repeated.

The New Yorker was silent for quite a while.

"What strange contradictions one finds in the West," he said, and the girl looked at him wonderingly.—*Detroit Free Press.*

A CHINAMAN lately returned from a trip to Europe treated his countrymen to the following description of the piano: "The Europeans keep a large four-legged beast which they can make sing at will. A man or more frequently a woman, or even a feeble girl, sits down in front of the animal and steps on its tail, at the same time striking its white teeth with his or her fingers, when the creature begins to sing. The singing, though much louder than a bird's, is pleasant to listen to. The beast does not bite, nor does it move, though it is not tied up."—*Das Neu Blat.*

CLERGYMAN (visiting prison)—So you were arrested for passing bad money, my man! Convict—Not exactly, sir! You see, if the money had passed I wouldn't have been arrested.

COMMUNICATIONS.

THE SURGICAL TREATMENT OF GENERAL PERITONITIS DUE TO THE DISSEMINATION OF SEPTIC PRODUCTS.*

OSCAR H. ALLIS,† M.D., PHILADELPHIA.

With the confident assurance that a patient has general peritonitis of septic origin, the surgeon of to-day does not hesitate to open the abdominal cavity, repair, if possible, the origin of the disease, and follow this with a thorough flushing of the infected region with properly tempered water; and with what result? Death so promptly and inevitably as to discourage both surgeon and physician from ever attempting it again. Yet such cases are purely surgical, and if any succor is ever to come to them it must be through open surgical measures. These two considerations have alone prompted me to bring this subject before the Academy to-night, and though I have nothing hopeful to offer in the way of practical experience, I hope in a comparison of this affection with kindred diseases to offer at least a suggestion for a future course of procedure.

At the outset, let me repeat that I shall have nothing to say upon the origin of the disease or the treatment of the primary lesion; my topic is the treatment of general septic peritonitis, from whatever cause it may arise.

First, is there anything in the nature of the peritoneal membrane itself that makes it so fatal? If we compare the diseases of the thorax with those of the abdomen the question can be answered in the negative. The pleura is originally a part of the general serous membrane and, of course, identical with that of the abdomen. Purulent pleurisies are treated to-day with great success. What are the conditions present and on what does the success depend? The conditions present are the covering of the entire lung and thoracic cavity with a foul, poisonous exudate and the pouring out into the thoracic cavity of a putrid, offensive purulent fluid. The accumulation is accompanied with pain, fever from the absorption of septic products, difficulty of breathing from mechanical interference, loss of appetite and emaciation, and, if unrelieved, death. The relief of such a case is simple and should be carefully inquired into. In its simplest form the treatment consists of free, dependent, unobstructed drainage. Under such treatment so many have gotten perfectly well that one must seriously ask if water is used to wash out the cavity, of what use it is. Water used upon an indolent leg ulcer may wash away the effusive accumulations; but it does not, surgically speaking, clean the ulcer. Water medicated, as a strong mercurial solution, does not surgically cleanse the ulcer. It may destroy the superficial layers of the diseased germ-bearing tissue and render a necessity for dressings less frequent, but to cleanse away the diseased semi-organized tissue the knife must be used and the whole cut away, or the curette employed and the surface scraped until a healthy base is reached. Then, and only then, have we removed the foul covering of the ulcer and obtained a surgically clean surface as a basis of repair.

When we use a simple or medicated fluid in the thoracic cavity we wash away, if the opening be sufficiently free and the stream ample, the dead effete products of the pseudo-membrane that lines the thoracic cavity and covers the lung. The washing does not purify, surgically speaking, the exudate, and even if we employ the so-called germicidal fluids, effect upon the pseudo-membrane is only upon its surface. It may, as in the case of the leg ulcer, diminish the quantity of pus and the frequency of dressing, but it cannot wholly eradicate or destroy the exudate.

Seeing, then, that recoveries take place in purulent pleurisies from drainage without washings, as well as from drainage with washings, the conclusion must inevitably follow that *the essential feature of treatment is drainage.*

But we must not omit a further inquiry

*Read before the Philadelphia Academy of Surgery, October 1, 1894.

†Surgeon to the Presbyterian Hospital.

into the case, namely, the nature of the pus cavity, for that it really is. The answer to this question is, I believe, the key to the success of treatment. In some cases the pus chamber is a simple cavity. The lung has shrunken and is far removed from the surface of the ribs. In this class there is no apposition of visceral surfaces and no hindrance to drainage, and if the openings are dependent and ample, the treatment will be unattended with relapse or annoyance. In other cases, owing possibly to previous pleurisies, there are pockets of pus, and imperfect drainage, at best, is obtained. In such cases the dead elements of the exudate are retained in pockets, and the result is imperfect, unsatisfactory response to treatment, and death, though delayed, finally ends the scene.

Let us now take up the conditions present in a purulent peritonitis. My subject demands that I treat this condition when it is full-blown and general; but before doing so I will delay a moment to show the analogy between a local peritonitis due to septic products and the condition present in a purulent pleurisy. In both a serous membrane is involved; in both the abscess cavity is walled off with pseudo-membrane; in both the recovery is chronic, and can only take place by the slow removal of the exudate and its replacement with healthy granulations, and in both drainage, free and unobstructed, is an uncompromising essential. The success of the operation for the relief of local purulent appendicitis depends not on washing out the cavity with antiseptic lotions, *but in preserving in its integrity the wall of lymph* that has been formed to limit the progress of the disease and prevent septic material from infecting the general peritoneal cavity. So long as a pus chamber can be kept patulous and the elements of decomposing pus and tissue readily removed, the progress of such cases is to health.

Now what are the conditions in a general peritonitis? Not one, but scores of pockets of poisonous matter—pockets everywhere —with lymph covering every *tissue* of the abdomen. To remedy this the surgeon enters with his hand and carries a clean warm fluid into every part of the cavity. He breaks open a great number of pus chambers and removes the ptomaines and leucomaines that are doing their deadly work. So far very well; but this to be effectual must be repeated. The washing does not purify the exudate—more effete products will be cast off and must be gotten rid of. Some means must be taken to prevent adhesions taking place, while at the same time the elements of putrefaction and necrotic waste must be removed. Whether drainage-tubes passed to the most dependent parts of the cavity, as a means of continuous flushing, would prevent reattachments, can only be learned by trial. Such a course will be of no real value if partial or trifling. The waste must be driven off and the stream kept up constantly night and day, until the normal surfaces have regained their tone and thrown off the exudate. Under a continuous system of flushing or irrigation, the waste products would be made to float constantly to the surface and be more effectually carried off than by dependent dossil drainage.

Such a course may commend itself to some surgeons, and as it has already been recommended in whole or in part, it will no doubt ere long receive a fair intelligent trial. To my mind the following seems more in keeping with nature's own plan.

As drainage is the basis of recovery in the allied conditions referred to, I cannot conceive of any adequate dependent drainage except a long median incision—kept open by proper packing—*with the patient prone* except at the times of dressing. To prevent the sides of the incision from closing or the intestines from uniting to the lips of the incision, rubber dam thoroughly covered with cerate could be tucked between the abdominal wall and the intestines on each side, with one border emerging from the incision. At the same time, to retard, if not prevent, adhesions of the contiguous coils of intestines, the whole serous surface could be well covered with a lubricant-like cosmoline or cerate. If the abdomen has been previously flushed with water, the cavity should be dried before the application of the cerate. Were it not that the adhesions tend constantly to form, I should be sanguine that the *prone* position alone, maintained constantly for weeks, would result in recovery. To guard against these, it would seem wise to reënter the cavity on the following day, and reapplying cerate to the walls of the cavity and the entire surfaces of its contents, redressing with rubber dam as before, again place the patient prone.

With dependent drainage, with an ample wound kept patulous, all water save such as is necessary to preserve outward cleanliness could be dispensed with. A difficulty might be experienced in keeping the patient in the prone position. This could be accomplished by means of a thin, well-padded strip of wood two or three feet long, strapped transversely to the pelvis.

Although this is the purest theory, it is theory based on successful treatment of allied affections. It is treatment of an extensive pus cavity with adequate dependent drainage. Drainage from the rectum or vagina may be serviceable when a local pelvic peritonitis is under consideration, but when general, nothing short of a long six-inch median abdominal incision will be adequate for the vast area of disease, and this only can do the work when the incision is freely patulous and made dependent by the persistent prone posture.

In closing, I wish again to call the attention of surgeons to the statement made in the beginning, that the disease under consideration is of a purely surgical character, and that the responsibility in a great measure of its successful management rests with them. Nothing more weighty, nothing more important demands their attention.

LIGATURE OF THE SPERMATIC CORD IN THE TREATMENT OF HYPERTROPHY OF THE PROSTATE GLAND.*

J. EWING MEARS, M.D., PHILADELPHIA.

In the male subject the function of the generative apparatus involves the secretion of semen, and, under certain conditions, its ejaculation. The former is accomplished in the testes and the latter by the vasa deferentia, the vesiculæ seminales, the prostate, the urethra and penis.

In order to explain certain forms of hypertrophic changes occurring in the prostate gland, I think it necessary to consider the anatomical structure of the ejaculatory apparatus. Portions of this are tubal in character, forming ducts or canals, as the vasa deferentia and urethra; the vesiculæ seminales are positive organs, not mere receptacles for the accumulation of semen, but possessing secretory power; the prostate is more of a muscular than a glandular organ. As determined by the investigations of Kölliker, the glandular substance does not constitute more than one-third or a half of the whole mass; the vasa deferentia, according to the same author, are endowed with a colossal muscular apparatus and are stated to be chiefly operative in ejaculation. The seminal vesicles and ejaculatory ducts exhibit the same muscular structure as the vasa deferentia. All parts of the ejaculatory apparatus possess what is essential to their functions—a redundance of muscular fibers. I refer to these well-known anatomical facts in orde that they may be considered in connection with certain forms of prostatic hypertrophy.

Enlargement of the prostate may be due to inflammation—acute or chronic—sometimes eventuating in abscess; cystic degeneration, which is rare; tuberculosis; myomatous growths; carcinoma; simple hypertrophy. Cystic, tubercular, and carcinomatous affections of the prostate may be eliminated from consideration on this occasion as being without the circle of conditions possible to be relieved or in any way affected by the plan of treatment to be discussed. The remaining affections clinical observations have, I think, satisfactorily determined as enjoying intimate relations with the functional activity of the secretive organs of the generative apparatus, and therefore affected by any conditions which control this.

An organ in a state of inflammation requires, in order that it may return to a normal condition, a cessation, so far as it is possible, of its function; if this is not accomplished the inflammatory action progresses, with the resultant effects of plastic deposit, increase in size, the course of the inflammatory action terminating in this stage, or possibly continuing to the suppurative stage.

In myomatous growths of the uterus

* Read before the Philadelphia Academy of Surgery November 5, 1894.

clinical observation records the fact that in married women, or in single women in whom the sexual activity of the generative organs is maintained, these develop more rapidly and attain a larger size than in the unmarried female or in the single female who does not indulge in sexual congress.

Clinical investigation has also determined the fact that simple hypernutrition is the result in many instances of overstimulation; of inordinate functional activity. In this manner it is possible to account for simple hypertrophy of the prostate, that condition which more than any other is responsible for the serious secondary conditions manifested in the urinary apparatus. With this condition the surgeon has to deal oftener than with any other form of hypertrophy occurring in the gland. Examination of specimens of prostate glands affected with simple hypertrophy shows, according to Billroth, that there is no increase in the glandular elements, but simply expansion of the acini and epithelium hyperplasia. The frequently observed enlargement of the gland depends essentially on diffuse myoma.

The question as to the occurrence of hypertrophic changes in the prostate gland at a period of life when on all other glands and tissues of the body the law of atrophy assumes sway, has often been asked, but never satisfactorily answered. May the answer not be found in its anatomical structure and in its anatomical and physiological relations? In structure and function it is composite. The arrangement of its muscular fibers would seem to indicate that their duty was more than that which relates to the function of the glandular portion of the organ—more than the simple expulsion of the secretion of the gland into the general ejaculatory canal. Placed near the culmination of the forces concerned in the expulsion of the spermatic fluid, its function would appear to be that of a reinforcing agent—of giving increased propulsive movement to the column of fluid which, it may be, comes only from the seminal vesicles or from both vasa deferentia and seminal vesicles. Is the hypertrophy, therefore, conservative in character, occurring at a period of life when nerve power declines and the other muscular portions of the ejaculatory apparatus yield to the law of atrophy?

It is my observation that the form of hypertrophy under discussion occurs in those who have over-indulged the sexual appetite—who have kept the generative organs in a prolonged state of excitement with, in many instances, incomplete acts, or without acts of coition, these conditions resulting in over-stimulation of the gland.

Coming now to the plan of treatment suggested in the title of this brief paper, it would appear to be both philosophic and physiologic, as an effort has been made to show that the pathologic condition present is directly associated with the functional activity of the generative apparatus. Obliterate this, and all organs associated in the production of this function will be affected. Without the organs for secretion of semen the ejaculatory apparatus has no function.

The eminent Rokitansky long since observed that the prostate is generally found to be small when the organs of generation are in imperfect condition, and a diminution of the prostate with relaxation of the glandular tissue has been observed as accompanying atrophy of the testes.

To obliterate the function of the generative apparatus is therefore a rational method of treatment in prostatic hypertrophy of the forms above mentioned. How can this be accomplished? Dr. J. William White, in an elaborate paper on "Surgery of the Hypertrophied Prostate," read before the meeting of the American Surgical Association in 1893, referred to the operation of castration as a therapu-e tic measure in hypertrophy of the prostate, and reported a number of experiments which were conducted on dogs, showing that removal of the testes in these animals was followed by prostatic atrophy. Without doubt castration would prove effectual in the production of atrophy, and the reports of cases have appeared in recent current surgical literature in which very positive relief was afforded by the operation. It is an operation, however, to which patients will naturally refuse to submit unless in the very last stages of disease of the bladder resulting from prostatic obstruction.

In the discussion which followed the reading of Dr. White's paper I suggested the ligature of the vas deferens as an operation which would probably be as efficacious as castration, and one which I believed would be more readily accepted by patients. I have seen the report of one case

in which this operation has been performed since that date with a successful result.

Within the last year I have taken occasion to examine patients on whom I had performed subcutaneous ligature of the vessels of the cord for varicocele, and I have observed more or less atrophy of the testes in these cases. In all the vas deferens was not excluded in the ligature. One patient, aged at the time of the operation eighteen years, reported that subsequent to the operation nocturnal emissions, from which he had suffered greatly, disappeared, showing, I think, the relief afforded to prostatic irritation by the operation.

Inclusion of the vas deferens in the ligature applied to the vessels of the spermatic cord would effectually, I believe, produce atrophy of the testes, and the operation is not increased in gravity. It might be advisable to apply the ligatures at intervals of time.

The gradual disappearance of the sexual function would not disturb the mental condition of the patient, as many realize it from other causes, and the consolation he would derive from the presence of the testicles, with relief from suffering, would, I believe, fully compensate. In all cases the patient should be informed of the character of the operation and what is intended to be accomplished by it. With him should rest the decision. I regard it the duty of the surgeon, however, to urge very earnestly the performance of any operation which will be efficacious in terminating the sufferings, sometimes horrible as they are, of patients suffering from the results of prostatic obstruction.

LITHOTOMY AFTER PARTIALLY SUCCESSFUL CLOSURE OF EXSTROPHY OF THE BLADDER—SUBSEQUENT CONSTRUCTION OF A PERINEAL URETHRA FROM SCROTAL TISSUE.*

JOHN B. ROBERTS, M.D., PHILADELPHIA.

In March, 1893, a child, aged eight years, with exstrophy of the bladder, was brought to me at the Polyclinic Hospital for treatment. The mother told me that when three or four years old he had been operated on at the Children's Hospital. It was evident that some improvement in the condition had been made by this early operation, because the posterior wall of the bladder did not protrude, as is often the case, but formed a rather shallow cup at the base of the rudimentary penis. The flaps had evidently been taken from the surface above the congenital defect and at its two sides, as in Wood's operation, for the cicatrices in these regions were apparent. The urine ran from the bladder over the penis and scrotum, and also escaped from linear sinuses along the top and sides of the thickened tissue which closed the upper portion of the cleft in the bladder.

As a first step in the operation I endeavored to produce a perineal fistula by thrusting a curved needle from the base of the bladder through the perineum, behind the scrotum, and conducting a drainage through the opening so made. The tube was increased in size at various intervals until at the end of two months there was a canal which would contain a rubber urethral bougie of moderate size.

I then etherized the patient a second time, and made a circular denudation around the edge of the open bladder. The rudimentary penis, consisting of the spongy body, the cleft glans and cleft prepuce, was entirely removed. Cylindrical masses on each side of the opening in the bladder, which appeared to be the representatives of the cavernous bodies, were also dissected away. A piece of soft rubber catheter was then introduced through the perineal opening established by the first operation, and its end allowed to reach the floor of the bladder. The purpose of this procedure was to secure downward drainage of the urine after the edges of the bladder were brought together.

Seven deep sutures were next inserted in a manner to bring the denuded edges of the bladder wall into apposition in a vertical direction. The wound was then sealed with iodoform and collodion.

* Read before the Philadelphia Academy of Surgery, November 5, 1894.

The perineal tube, however, soon became blocked with muco-pus, which was continually flowing from the irritated mucous membrane of the bladder, and was not satisfactory as a drain. I finally passed a drainage-tube from one of the upper sinuses directly through the bladder and out of the perineal opening, in order to prevent the sutures in the middle line from yielding. These middle sutures, however, finally gave way, and when the patient passed from observation there was a large opening in the middle of the attempted closure. Some union had, however, been obtained. The perineal opening showed a marked tendency to close.

I did not see the patient again until October, 1894, sixteen months later. At this time the perineal opening had entirely closed and its scar was inconspicuous, but the exstrophy of the bladder was completely covered by the new anterior wall. At about the middle of this wall, which had been constructed in the manner described, was a small opening of sufficient size to admit the end of a large probe. At the upper and right-hand side of the portion of the wall which had been constructed in infancy was a linear sinus about an inch in length. This was situated at one of the points which, when I first saw the child, allowed the urine to escape. There was a little oozing of urine from the small central fistula, but the major portion escaped from the sinus at the upper right-hand border.

The mother said that the patient suffered severe pain, which was evident by his crying at the least touch of the skin in the neighborhood of the central sinus. The insertion of a probe made it evident that the new bladder contained calculi. The child's general condition was poor, and it was evident that he had been suffering greatly. The offensive character of the urine and the difficulty of keeping him free from its odor caused me to give him small doses of turpentine, which, as is well known, imparts a peculiarly agreeable odor to the urine. This device seemed to render the patient less offensive to the others in the ward.

A few days later I enlarged the opening in the middle of the bladder wall in front and found the cavity filled with calculi. They were ten in number and varied from five-sixteenths to five-eighths of an inch in diameter. Their combined weight when not dried was 195 grains.

It seemed to me that the establishment of a perineal urethra lined with skin would afford efficient drainage to the new bladder and would remain patulous. I therefore determined to cut a channel between the perineum and the floor of the bladder, and turn in flaps of skin taken from the scrotum. As a first step I incised the scrotum in the middle line and removed both testicles. I then made a puncture downward from the base of the bladder to this scrotal incision. This permitted me to utilize the scrotal tissue for lining the new channel. By two horizontal incisions on each side of the opening I obtained strips of scrotal skin and superficial fascia half an inch wide and an inch and a half long. To the inner end of these, ligatures were fastened and the threads carried upward through the new urethra. The cutaneous flaps were then drawn up along the canal into the bladder, and were then sutured on each side of the incision in the middle line of the anterior bladder wall. This maneuver lined both sides of the perineal opening with skin from the perineum to the anterior bladder wall. A drainage-tube was inserted to keep the channel patulous, and the bladder and tube were washed out.

No attempt was made to close the opening in the middle line or that at the upper and right-hand side. I deemed it better to leave these open for convenience in flushing the foul bladder cavity. It was my intention to close these at a later period. The edges of the wound in the perineum left by the plastic operation were brought together with sutures, and healed promptly. Antiseptic solutions were used for washing out the bladder and tube, and the patient did well for several days. His temperature was not high, and the drainage through the perineal tubes was quite satisfactory, though not always perfect. At the end of three or four days he began to lose his appetite and vomited occasionally. He died on the fifth day, apparently from exhaustion.

An autopsy showed disease of the left kidney, which was riddled with small abscesses. The ureter on this side was double, and showed great enlargement of the caliber and thickening of the walls. The pelvis of the kidney and the double

ureter were filled with pus. Just before the two ureters of this kidney reached the bladder they united and opened into the bladder by a single orifice. The right kidney and ureter appeared to be normal.

The specimens presented will make the description of the case clear, since Dr. Bannister, the resident physician, removed the whole bladder and scrotum with the attached ureters and kidneys. I believe this method of constructing a perineal urethra and lining it with skin from the scrotum will be found an efficient device in dealing with these unfortunate cases. It is very probable that the child would have lived if I had taken this step originally, instead of making an opening into the perineum without cutaneous lining.

TRANSLATIONS.

THE MEDICAL TREATMENT OF CANCER OF THE STOMACH.*

Plicque (*Gaz. Méd. de Paris*, July 28, 1894) remarks that at first sight the treatment of cancer of the stomach seems illusory and discouraging. Patiently directed, it may, nevertheless, effectually combat the pain, the hematemesis, the digestive troubles and the progressive cachexia. The cancerous tumor may be simulated by an epiploic inflammation, an accumulation of fecal matter in the transverse colon, and even by a simple partial contraction of the recti muscles. Having made the diagnosis the following treatment may be instituted.

1. For the pain the vesicatories may be employed, the hot iron point, the morphine vesicatories, local applications of chloroform. Among the most efficacious external applications are the actual cautery and applications of hemlock. The cautery not only controls the pain, but often also the dyspeptic troubles. The only precaution in the case of the existence of a growing tumor near the skin is to apply the cautery at some distance. If this be not observed the complication well noted by Feulard, namely, gastro-cutaneous fistula, may be produced. Applications of hemlock or of a pomade of the extract of hemlock are valuable in controlling the pain. A useful precaution is to recommend to the patient not to touch the eyes after having handled these preparations; very often painful visual troubles may result from this cause alone. Subcutaneous injections of morphine should not be employed unless the diagnosis of cancer is absolutely certain. It will often aggravate dyspeptic troubles. Condurango employed internally will permit the physician often to escape recourse to injections of morphine. Its sedative action is such that some German authors have attempted to make condurango a means of diagnosis. One of the best modes of preparation is the infusion. It is prescribed as follows:

Fresh bark of condurango, 15 grams; infuse for fifteen minutes in 30 grams of water; take in teaspoonful doses.

The alcoholic tincture may also be prescribed: Alcoholic tincture of condurango, 10 grams; gum julep, 120 grams. Teaspoonful doses.

Or simply the powder may be given: 50 centigrams in a cachet, of which six to eight may be taken daily.

2. *Hematemesis.*—The hematemesis of cancer is ordinarily slight in amount and repeated. Melena is more frequent than hematemesis. It is rarely required to treat a large hemorrhages as in ulcer, but the small hemorrhages should be energetically treated because they are the great cause of the cachexia. One may employ as the principal means: (*a*) *Acidulated drinks*, especially the weak hydrochloric solution, as 2 to 1,000, of equal service in dyspepsia. (*b*) Parden intended to make a sort of dressing for the gastric ulceration. Peter's formula is excellent: Crude opium, 0.02 centigram; subnitrate of bismuth, 2 grams; make into a paper; one paper before each meal. Antipyrin in cachets of 1 gram constitutes also a very good hemostatic agent. While lavage of the stomach in cancer may be made, it is wiser to abstain from them.

* Translated for THE MEDICAL AND SURGICAL REPORTER by W. A. N. Darland, M.D.

3. Against the dyspeptic troubles the weak hydrochloric solution, strongly indicated by reason of the hypochlorhydria of cancer, and condurango, especially of service in case of gastric catarrh (watery vomiting of cancer), have been already mentioned. Sodium chlorate, recommended by Brissaud, gives in some patients most excellent results. This salt, being slightly toxic, may be given in doses of 12 grams or more daily; ordinarily 4 to 6 grams are given. It is very soluble and may be easily taken in milk. On account of the disagreeable taste some patients will only take it in cachets. In the case of excessive gastric fermentation the employment of the weak hydrochloric solution, chloroform water diluted to a third, and intestinal antiseptics must be employed. One of the best antiseptics, as has been shown by Gilbert, is benzo-naphthol, which is well tolerated by both the stomach and the kidneys. Daily, after the meals, 2 to 8 cachets of 50 centimeters each should be given. Magnesia is a drug very inoffensive and very useful in doses of 2 to 4 grams daily. For the vomiting the ordinary measures must be adopted: Seltzer water, Rivière's potion, champagne, ice. Gavage, the tube not being introduced further than half-way down the esophagus, is very valuable in uncontrollable vomiting. Anorexia is not controlled by any remedy save perhaps condurango. Gavage constitutes a useful extreme resource. The diet must be attended to and the ordinary laws of general hygiene observed—friction of the skin, moderate exercise, plenty of fresh air. Hydrotherapy and massage are very useful to maintain a certain tonicity and a seeming vigor.

CORRESPONDENCE.

REMINISCENCES OF DR. HOLMES.

DEAR DR. KYNETT:

Your kind, urgent and repeated request for me to give you some reminiscences of Dr. Oliver Wendell Holmes can no longer be refused. But let me insist that if you publish what I write my name be omitted, for I abhor any apparent seeking of notoriety by having that name appear in connection with the illustrious dead. So many doctors take "trade" ways of getting their names before the professional and the lay public that I am anxious to avoid even the semblance of the sin.

My acquaintance with Dr. Holmes was chiefly through correspondence. Only once did I have the privilege of a long interview, but at that time he was, according to a mutual Boston friend who was with me, "in his best vein," a very fortunate fact for me. Of that interview I shall speak presently.

Dr. Holmes was so kind, so considerate, so self-sacrificing and helpful to me on more than one occasion when I made appeal, that my debt of gratiude was great. I admired and loved him and his memory is very precious. Many a year ago I sent him a copy of an address upon the Odyssey as illustrating the trials and temptations, the difficulties and dangers of life, and he replied, thanking me for the pamphlet, giving kind commendation and adding that he always read the great poem for "pleasure, never before thinking of a moral in it."

A few years afterward it was my duty to deliver an address before an important medical organization, and I had selected a subject possibly too ambitious for my ability, but was especially desirous that there should be no flaw in the logic and no failure in the rhetoric. Before its delivery I therefore had proof slips sent to Dr. Holmes and to the Rev. Dr. McCosh—alas! he too is gone—requesting from each his criticism. Both these eminent men kindly responded, and of course my work was greatly improved by their suggestions and advice.

The last letter he sent me was written on the third day of last January, and is as follows:

"DEAR DR. ——:

"I have just finished reading, and reading carefully, your lecture containing an account of the great obstetrician of two centuries ago, De la Motte. It

is long since I have read a medical article which gave me so much satisfaction. I have always thought a good deal of wise 'country doctors,' and La Motte appears as one of the wisest and best, whose writings are well worth recalling in the midst of the swarms of medical authors who are crowding each other in the pursuit of fortune and fame."

Between the reception of the letter you published in THE MEDICAL AND SURGICAL REPORTER a short time since and this now given, several intervene—I never wrote to him that he did not kindly and promptly respond—but I doubt if any of them are of sufficient professional interest to be published in a medical journal.

The interview to which reference has been made occurred in 1878, the month September. A few minutes after my entrance into his house and the following brief conversation which I cannot now recall, he took me to one of the windows of the room where we were sitting, back room of second floor, and pointing across the Charles River, showed me the penitentiary, saying, "There is where we put our bad men," and "there," pointing to Harvard, "is where we take our good men and make doctors of them." Resuming our seats, he picked up a slim book, bound in red muslin, apparently fresh from the publishers, and said, "Here is a book of poems that has been sent me, and indeed it has some merit. Unfortunately in this age and in our country every young man or young woman who can make two lines, one ending in dove and the other in love, thinks that he or she is a poet. There are two diseases which I could never cure, hydrophobia and writing poetry."

Further on in the interview he remarked: "I have been to see old Dr. Jacob Bigelow this morning—I generally go to see him once a week—and as I was leaving him he said, 'Dr. Holmes, if you find any one happier than I am, please let me know.' And there he is, more than eighty years old, blind and bed-ridden, but he is happy." I ventured to ask Dr. Holmes, what is the secret of his happiness? He immediately replied, "What is the secret of all happiness? Temperament. If a person has good digestion, moderate desires and wants, and these are met, he will be happy." But, said I, not perfectly satisfied with this definition of happiness, what is to be done for those who have not good digestion, whose wants are not satisfied, desires not gratified? His reply came after a little hesitation and with a tone of sadness, "I suppose they will have to die."

About this time my dear friend, that noble man, Dr. Fordyce Barker, came in and one or two others with him, and the conversation flowed in various eddies, the new guests contributing much to it. Dr. Holmes, of course, was the chief speaker still. He referred to Moody and Joseph Cook and Phillips Brooks, the last of whom he greatly admired. He quoted the refusal of Mr. Brooks to ask a blessing at the table of a gentleman who avowed that there was not much at his meals, respect for his guest, not for the good Giver of all, being the motive for asking. He also quoted the remark of a Boston lady—this remark appears also, I believe, in one of Emerson's essays—"A well-dressed woman is in the enjoyment of a happiness that religion cannot give." A different kind of happiness indeed, but by no means the highest.

The two hours passed swiftly in the company of Dr. Holmes, but their brightness has not been dimmed by the lapse of twenty-six years. They were among the happiest of my life.

Didn't Choose Him.

Mother—To think that my little Ethel should have spoken so impertinently to papa to-day at dinner! She never hears me talk that way to him.

Ethel, stoutly—Well, you choosed him and I didn't.—*Brooklyn Life.*

"THE trouble with this world, Raggsy," said Walker, the tramp, "is just here. In Central America bananas grow wild, but there ain't no markit for 'em. Up here where there is a markit for 'em they don't grow wild. What nacher wants to do to help the workin'man is to have things grow wild where there's a markit for them things."—*Harper's Bazar.*

TOO MANY PEANUTS.—A New York woman died on Saturday of peritonitis, brought on by eating peanuts. During the week she ate several quarts and at the post-mortem examination a quart of undigested peanuts was found.

EDITORIAL.

CRIMINAL ABORTION.

Questions of obstetric morality and of the criminal responsibility of medical practitioners in cases of abortion are constantly receiving the attention of medical and legal writers.

With the advance of medical and anatomical knowledge the law reaches higher and juster ground in the matter of obstetric skill, and many old delusions are now swept away. Naturally many elements enter abortion cases and, therefore, not a little confusion and conflict in the decisions bearing upon them. It requires careful sifting of judicial rulings as applied to particular cases, each with its own peculiar incidents and elements, to get the sound law governing in all such cases. These cases stain many pages of court records.

The vicious idea is not yet entirely effete that there is no offense in destroying the embryo, or fœtus, before there is a manifest knowledge of life, before the mother can feel the muscular motions of life. This absurd notion is fully exploded in medicine, but it still lingers in the popular mind and doubtless leads to much crime.

Quickening is but a new manifestation of preëxisting life. The life of the fœtus, or embryo, immediately after conception is just as positive, physiologically, as at any subsequent period, and ante-quickening fœticide has been made penal by the statutory enactments of many of the States. A leading English case establishes the position, upon grounds logically and legally sound, that the child exists legally from and after conception.

The criminal attempt to destroy the fœtus at any time before birth is termed in law a miscarriage, varying in degree of offense and punishment, whether the attempt were before or after the child had quickened and according as declared by statute. The term miscarriage is in effect identical with the destruction of the fœtus.

The crime of attempting to produce the miscarriage of a pregnant woman is complete if the attempt is made at any time during pregnancy.

Much confusion arose from early judicial findings in some of the States to the effect that it never was a punishable offense at common law to produce, with

the consent of the mother, an abortion prior to the time when the mother became quick with child. It was not even murder, at common law, to take the life of the child at any period of gestation; even in the very act of delivery. To remedy this adjudged defect in the law, Massachusetts, New Jersey and other States passed remedial statutes.

The Supreme Court of Pennsylvania did not so interpret the common law. It says, in a strong and elaborate opinion: "The moment the womb is instinct with embryo life and gestation has begun, the crime may be perpetrated." And further, that "when a female is with child and a potion is administered to her for the purpose of destroying the child, which produces the death of the mother, it is murder in the second degree unless there existed in the perpetration of the mischief an intent to take away the life of the mother as well as to destroy the offspring, in which case it would be murder in the first degree."

That which has been laid down as very old English law gives strong support to this opinion. More than two hundred years ago Lord Hale, one of the purest, most honored and eminent of English jurists, interpreted the law as follows:

"If a woman be with child, and any one gives her a potion to destroy the child within her, and she takes it and it works so strong that it kills her, this is murder, for it was not to cure her of a disease, but to unlawfully destroy the child within her, and therefore he that gives a potion to this end must take the hazard, and if it kills the mother it is murder."

By the well settled and established doctrine of the common law, the civil rights of an infant *in ventre sa mère* are fully protected at all periods of gestation.

It may be concluded that any attempt to procure abortion, even when the pregnant woman is not quick with child, is a misdemeanor at common law, and when the mother is quick it is a felony.

Miscarriage, both in law and philology, means the bringing forth of the fœtus before it is perfectly formed and capable of living. The word abortion is synonymous with miscarriage in its primary meaning. It has a secondary meaning, in which it is used to denote the offspring. Any person who does any act calculated to prevent a child from being born alive is guilty of abortion.

It is not alone for the reasons that this offense is one against morals and decency, that it is in wanton disregard of moral and social duty, that the law so severely condemns it, but "because it interferes with and violates the mysteries of nature in that process by which the human race is propagated and continued. It is a crime against nature which obstructs the fountain of life and therefore it is punishsd. It is not the murder of a living child which constitutes the offense, but the destruction of gestation by wicked means and against nature."

The means by which abortions are procured are many. It is dangerous to the life and health of the mother and to the existence of the child to experiment with any drug, medicine or noxious thing to produce miscarriage. Ignorance may lead to the selection of something that will not produce the effect designed, but if it be noxious in any degree, though in the judgment of others who have greater knowledge it cannot produce the effect intended, it is criminal. If a person with a criminal intent use any substance to produce a miscarriage he will not be held innocent because he mistakenly administered a drug or substance which did not produce the result intended. It is the *intent* and not the *substance used* that determines the criminality. Guilt is not determined by the success or failure of the attempt, but the *measure of the punishment* is graduated by the fact whether the woman

lives or dies. The law, in its solicitude for the sacredness of human life and the personal safety of every human being, guards the health and life of the female against attempts to procure abortion.

The spirit of the law is forcibly declared in a Supreme Court decision interpreting the Massachusetts statute. It was held that it was not required to prove what the medicine was, or whether it would produce the effect intended, or whether it was actually taken by the woman, nor that the liquids and pills procured for her and which she was advised to take for the *purpose of producing* a miscarriage were noxious things. The reasoning of the Court is that it may well be that the Legislature has thought fit to punish persons for thus tampering with a woman's health and life, though they may be utterly mistaken as to the character and effect of the medicine; and if it were necessary to prove the quality of the medicine it might often be difficult to convict offenders who had used the most noxious drugs. The fact is well recognized in law, as it is in medicine, that the willful and unnecessary procurement of an abortion is an act highly dangerous to the mother, and generally fatal and frequently intended to be fatal to the child. If with gross ignorance of the subject any one, from the desire of gain, undertakes a case and in consequence death ensues, it is clearly a homicide, by no means either justifiable or excusable. The law admits of no doubt.

The question whether the physician is regularly educated or not does not apply. A regular medical education may furnish a defense which an uneducated person could not have. The only question is whether in point of fact the physician or operator was ignorant of what he was about, and whether that ignorance was the cause of death.

If a man with a most extensive practice were to take cognizance of a particular case of which by his treatment he showed that he was clearly ignorant, his great practice would not be any excuse. The law, though gold lined through by many of our Christian charities, does not, of late years, mitigate the severity of its penalties in these cases. It is recognized how exceeding great is the number of people easily persuaded to put confidence in the itinerant quack and to trust their lives to strangers without knowledge or experience, who yield to the impudent pretensions of ignorant empiricism; therefore the need of severe remedies.

Has there been that healthy growth of the moral sense of the profession and the community on this subject which we have a right to expect in communities setting up high claims to chastity, to all the social virtues, to Christian morality?

The words of Hugh L. Hodge would make profitable reading from a high moral standpoint for the women of our land. The facts are too well known to the medical profession for their ignoring. He says: "This low estimate of the importance of fœtal life is by no means restricted to the ignorant or to the lower classes of society. Educated, refined and fashionable women—yea, in many instances, women whose moral character is, in other respects, without reproach, mothers who are devoted with an ardent and self-denying affection to the children who already constitute their family—are perfectly indifferent respecting the fœtus in the uterus. They seem not to realize that the being within them is indeed *animate;* that it is, in verity, a human being, body and spirit; that it is of importance; that its value is inestimable, having reference to this world and to the next. Hence they in every way neglect its interests. They eat and drink, they walk and ride, they will practice no self-restraint, but will indulge in every caprice, every passion, utterly regardless of the unseen and unloved embryo. They act with as much indifference as if the living, intelligent and im-

mortal existence lodged within their organs were of no more value than the bread eaten or the common excretions of the system. Even in cases where mothers from repeated abortions, where fœtus after fœtus has perished through their neglect or carelessness, and when even their own health is involved in the issue, even in such cases every obstetrician can bear testimony to the great difficulty of inducing our wayward patients to forego certain qualifications, to practice certain self-denials, and to adopt efficient means for the salvation of the child. This is not all. We can bear testimony that in some instances the woman who has been well educated, who occupies a high station in society, whose influence over others is great and whose character has not been impugned, will deliberately resort to any and every means which may effectually destroy her unborn offspring. Ashamed or afraid to apply to the charlatan who sustains his existence by the price of blood, and dreading publicity, she boldly and wickedly adopts measures, however severe and dangerous, for the accomplishment of her unnatural and guilty purpose. She will make extra muscular efforts, by long fatiguing walks, by dancing, running, jumping, kept up as long as possible; she will swallow the most nauseous, irritating and poisonous of drugs, and in some instances she will actually arm herself with the surgeon's instrument and operate upon her own body, that she may be delivered of an embryo for which she has no desire and whose birth and appearance she dreads."

Horrible! "and pity 'tis, 'tis true."

ABSTRACTS.

LESSONS LEARNED FROM ONE HUNDRED ABDOMINAL SECTIONS.

F. BYRON ROBINSON, M.D.

1. That chloroform kills outright by affecting the heart or respiratory center.

2. That ether may be followed by bronchitis and nephritis (immediate or remote).

3. That opening the peritoneum produces a raging thirst which can be slaked by one-half to two ounces of hot fluid an hour. Ice is dangerous and cold water should not be used after abdominal section.

4. That saline purgatives are prophylactic against incipient peritonitis. General peritonitis once established is practically an incurable disease.

5. That it is infection that tends to destroy life, while peritonitis tends to save life by throwing out exudates to prevent the invasion of infection. Local peritonitis is nature's method of repair.

6. That the three great regions of peritonitis are: *a*, the pelvic; *b*, appendicular; *c*, the region of the gall bladder They resist the invasion of infection and tolerate it markedly.

7. That infection among the small intestines is very fatal, from inability to produce peritonitic exudates to circumscribe the infection.

8. That gonorrhœa is the cause and sustaining factor of the majority of persistent tuboovarian diseases or pelvic peritonitis.

9. That gonorrhœal appendages are apt to infect ligatures which may suppurate and produce a fistula from one month to one year after the operation.

10. That post-operative hernia of the abdominal wound is liable to occur in malignant or aged cases. That advanced malignant visceral diseases should not be molested.

11. That irrigation and drainage of the peritoneal cavity should be limited—irrigation quite limited and drainage to hemorrhage and pus cases.

12. That the Trendelenberg position enables one to do more perfect work by seeing with the eyes and giving wider space for manipulation.

13. That suppurating appendicitis can

be radically cured (for two years at least) by an incision close to the right iliac fossa, allowing the pus to escape and not searching for the appendix. The incision can profitably be made close to the iliac spine.

14. That in woman the appendix is in the pelvis in one-third of the cases and tuboövarian and appendicular disease may each be derived from the other.

15. That inguinal hernia can be radically cured by restoring the obliquity of the inguinal canal and removing the spermatic cord into a new canal (Marcy, Bassini and Halstead).

16. That femoral hernia can be radically cured by displacing the femoral vein and artery toward the iliac spine and suturing the lower border of Poupart's ligament to the pectineal fascia—making a new canal for the vein and artery (Fabricius).

17. That tying off the appendages and then ligating the uterine artery as it courses along the uterus as far down as the cervix: *a*, quickly stops menstruation; *b*, checks hemorrhage in the uterine myoma; *c*, atrophies uterine tumors by cutting off the blood stream; *d*, by ligating the whole broad ligament low down with locked stitches the retroverted uterus can be well elevated; and *e*, by ligating the nourishing nerves, atrophy of the genitals will ensue.

18. That the fimbriated end of the Fallopian tube closes in two ways during the course of disease: *a*, in one case (disastrous) the tubal fimbriæ are only partially turned back into the tubal lumen, leaving infected fimbriæ both in the tubal lumen and in the peritoneal cavity—such cases are constantly liable to recurrent infection and exacerbation because the mucal fimbriæ serve as a home for the germs; *b*, the other (favorable) method is where all the fimbriæ of the tube are turned back into the tubal lumen, where they lie coiled up like the petals of a rose.

19. The very severe forms of menstrual neurosis can be cured (for two years) by removing the uterine appendages close to the uterus. Bleeding myoma is also in some cases cured by the same process.

20. But in reoperating on abdominal cases (one ten months, the other fourteen, after) for parovarian cysts, the viscera are found surrounded by various degrees of adhesions. The fourteen months' case possessed dense and extensive adhesions. I proved the same fact on scores of dogs' viscera several years ago.

21. That parovarian cysts are the most liable to recur in 100 cases of abdominal section.

22. That abdominal fistula is apt to arise immediately after the operation and continue for some weeks to eighteen months. Also that some fistulæ arise from two to six months after the operation and continue for eighteen months.

23. That urea is the best standard for safe laparotomy, as far as regards the kidney. When the woman came to the hospital the urea varied from five grains to twelve grains to the ounce, but in a few days it would become about eight grains to the ounce. Not so much notice is paid to albumen or sugar.

24. That in ruptured ectopic pregnancy there is surgical hope, though the temperature is nearly 107 and the pulse 160.

25. Every case of abdominal section should be in bed at least three weeks.—*J. A. M. A.*

Pinning Him Down.

She—Why didn't you come around last night?

He—I didn't get through at the office until so late that I hadn't time to go home to dress, and I didn't like to call in my business suit.

She—Why not? Don't you mean business?—*Detroit Free Press.*

An Idea.

Bobbie—Papa, I've been reading a story about an elephant drawing up a lot of water and then squirting it all over a man he didn't like.

Bobbie's Father—That wasn't a very nice thing to do, was it?

Bobbie—No. I should think he would have made him check his trunk.—*Harper's Young People.*

"CAN you give me a little breakfast, ma'am?" pleaded the tramp. "I'm hungry and cold. I slept outdoors last night, and the rain came down in sheets." "You should have got in between the sheets," said the woman kindly as she motioned him to the gate.—*Boston Home Journal.*

SOCIETY REPORTS.

NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS.

On November 15th, at the New York Academy of Medicine, this association held its fourth annual meeting.

The attendance of members was large. In addition there were several well-known surgeons, not resident in New York City, as participants and invited guests. Among such may be mentioned: Dr. W. L. Estes, of South Bethlehem, Pa.; Prof. A. P. Grinnell, of Vermont; Prof. John B. Murdock, of Pittsburg, Pa., and Prof. J. S. Wight, of Brooklyn, N. Y.

The principal topic which engaged the attention of the association was the subject of amputation. As the title had it, "Shall we amputate or shall we wait?"

The president, Dr. M. Cavana, of Oneida, presented an address on "Important and Unsettled Questions in Railway Surgery."

Dr. W. L. Estes opened the special discussion by reading a highly interesting essay on amputation, taking the affirmative for early interference and primary amputations. By a rigid adherence to aseptic methods the mortality of amputations might be very greatly reduced, and the speaker gave the statistics of more than three hundred cases in his own practice with a mortality of but a fraction over four per cent. He would not amputate in deep shock, and showed by figures that during the past six years, since conservative methods were introduced, his mortality was diminished more than fifty per cent. He believed that when one was in good condition after a serious crush of a limb, if an amputation was to be performed there was no advantage in waiting. He would be guided generally by the condition of the patient in deciding whether to operate immediately or wait.

Dr. Murdock opened the discussion on Dr. Estes' essay by saying that he had come with a paper prepared to submit, but Dr. Estes had so accurately and fully expressed his views that he would forego reading it and say but a few words only. He was entirely in accord with what had been said with reference to conservation, and agreed that when a limb was badly crushed and the question of severance was raised, the time to amputate was at once, as the dangers of infection and hemorrhage more than counter-balanced whatever advantage might follow delay. He had no faith in that line of surgery which exposed the patient to prolonged sufferings and then left him with a useless joint or limb. He cited Dr. Packard, of Philadelphia, who had declared that the saving of one limb might embolden practitioners to depend on such conservative means as would cause the sacrifice of a hundred lives.

Dr. Wight commenced by declaring that the discussion of medico-legal questions had no place at a meeting of surgeons. He then defined what, in his opinion, constituted a surgeon, alleging that one might be a good surgeon and yet know something of medicine, but that one might be a thoroughly competent physician and yet a very indifferent surgeon.

Since the introduction of anæsthetics surgeons had overlooked the importance of time in all operations; this was particularly true of amputation. In those who had sustained amputation in consequence of accident, when their general condition was good there should be little or no mortality. He had always observed that shock was in proportion to the loss of blood and the time occupied in amputating. It was his practice when a badly mangled limb came under his care to quickly effect a severance of it rather than wait until inflammatory changes set in.

Dr. Grinnell acknowledged that he was a physician, occupying a higher branch of the healing art than surgery. He had much to do with railroad surgeons in his capacity as an official for several railroad companies.

He believed that on the whole surgery had but very slightly, if any, reduced the mortality of amputation since the time of Celsus; certainly there was little or no difference in mortality now and in the time of the late war, when he was enabled to participate in a large number of amputations. He would most certainly insist on the greatest conservatism being always observed and every effort tried before a limb should be consigned to the amputating knife.

Dr. Manley opened his side of the question by first presenting short reports on six cases of serious mangling lesions of the extremities, complicated by such internal

injuries that none survived more than thirty hours. All were from railroads and had come into his service in the hospital during the preceding month. Next he submitted a patient for examination who three weeks before had his right elbow joint torn widely open and the soft parts entensively damaged. He said he exhibited him in order to show what might be accomplished, even in the most desperate cases, when we understand how to utilize conservative measures. Then a number of cuts and photographs were exhibited, illustrating various grave types of traumatisms, in which all the extremities were saved.

In opening his address on "Conservatism as a Fundamental Factor in Amputation," he said that he approached the consideration of the side assigned to him with diffidence, because his views might seem revolutionary and radical, and besides, four speakers had preceded him on the opposite side. The subject was a large one; he had written at some length on it, but as the time was limited he would but submit a few postulates and request the attention of the members to but a few features of the question. In the beginning he would say that though Dr. Estes' paper abounded in the most remarkable contradictory and inconsistent statements, yet he regarded the body of it as the strongest support that could be given to the position he would himself take.

He would agree that it would be both cruel and almost criminal to amputate in the presence of serious internal complications or when a patient was in profound shock, but he would go a long way further and insist that in civil life primary amputations should be wholly discarded. Esmarch's indications for amputations under fire in war might perhaps be accepted, but they certainly have no place in time of peace, for it should not be forgotten that amputations are often undertaken for other purposes than to save life. In the vast majority of instances we utilize them simply to aid the processes of nature in separating dead from living tissues and favoring the formation of a useful stump.

Immediately after a limb is crushed it was quite beyond the power of any surgeon to determine with precision the exact point of the vital line, and therefore one might go too high and needlessly sacrifice healthy structure, or too low and be obliged later to do a consecutive amputation.

In all cases, unless the parts had been traumatically amputated, enough would be accomplished if we effected complete hæmostasis, thoroughly cleansed the parts, brought the limb into a comfortable position, applied appropriate dressings and then waited until we were able to see whether the damaged limb were but temporarily asphyxiated or totally devitalized, or until the demarcating line was evident.

Resection of bone and articulation had come to largely replace amputation in pathological conditions during the past twenty-five years, and with marvelous success. During the closing years of our late war, through its utilization it had come to quite generally displace amputation, so that in this manner thousands of limbs were spared which formerly were sacrificed.

Amputation, he declared, was very often performed altogether too precipitately. As it always entailed the irreparable loss of a limb, it should not be lightly undertaken and never without consultation. Our own reputation, our patient's well-being, and often corporate interests equally imposed on us the importance of never performing an amputation until all the aids of science had been faithfully tried; and the resources of art were to be exhausted before this last and extreme procedure was resorted to. He would emphasize it, too, that the rules and principles which should guide us in the performance of amputations for pathological conditions must be quite wholly ignored in traumatisms.

At the afternoon session Dr. F. A. Stillings, of Concord, N. H., read a paper on "Asepsis and Antisepsis in Surgical Work," and showed by a large number of observations that there was a less tendency to suppuration in wounds when rigid asepsis was employed.

"Special Features of Railway Surgery" was the title of a paper by Dr. C. B. Herrick, of Troy. The other two papers were by Drs. J. A. Van Duzen, of Syracuse, and R. S. Harnden, of Waverly, and were given specially to the consideration of railway surgery.

The officers elected for the ensuing year are: Dr. R. S. Harnden, of Waverly, president; Dr. C. B. Herrick, of Troy, vice-president; and Dr. J. F. Valentine, of Brooklyn, treasurer.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE ALIENIST AND NEUROLOGIST for October. Dr. John Harold reports a

Case of Myxœdema Successfully Treated by Thyroid Gland.

The patient was a man fifty-one years old, unable to recall any of the usual predisposing influences. His habits were temperate.

The patient first noticed a clumsiness in handling objects, that his feet were habitually cold, that he was growing stouter and weaker and therefore unfit for his customary hard work, and had for several years suffered from chilblains.

For three or four years his friends remarked the change in his appearance. When seen he had the swollen and expressionless face, thin and peculiarly arched eyebrows, wide nostrils with thickened alæ and flat nose of an advanced case of myxœdema

The hair of the scalp was scanty and dry; parts of the scalp were bald, the axillæ and pubic regions free from hair. The tongue was enlarged and moved slowly, the teeth loose, the gums spongy and receding. The skin was sallow, thickened, harsh and dry and free from any sebaceous secretion; the nails brittle and grooved. Hands and feet were enlarged but not spade-shaped.

Movement, thought and speech were slow, the voice was husky, and little interest was shown in the surrounding life.

Complaint was made of a bitter taste and disagreeable odors.

The thyroid gland could not be outlined. The urine was pale and free from sugar and albumen. There was sensitiveness to cold, but nothing else abnormal could be found.

The average temperature of the body was 97.8°.

A glycerine thyroid extract was used hypodermically and then stopped on account of the pain and abscesses resulting. Five-grain tabloids of extract were then given by the mouth, and improvement soon began and all the symptoms abated.

By keeping the patient in bed he is completely under control, and the unpleasant effects which sometimes arise from thyroid treatment are readily noted and easily relieved.

The symptoms of over-use of this drug are palpitation, neuralgic pains, giddiness, nausea, headache, attacks like angina, etc. If the patient have any cardiac derangement the commencing doses must be small.

Other papers in this issue are: "Hallucinations and Delusions," by Dr. Wm. M. McLaury; "Uranism and Pæderasty," by Dr. Dimitry Stefanowsky; "Psychiatry and Brain Localization," by Dr. Arthur E. Mink; "The Origin and Progress of Mental Medicine," by Dr. E. Regis.

Continuous General Psycho-Motor Paresis,

by Dr. C. H. Hughes.

The author has seen several cases of psycho motor paresis which were neither precursors of general paresis nor results of general neurasthenia or cerebrasthenia. One is reported as follows: A slender man, sixty years old, with a doubtful history of syphilis, appeared stuporous and inert. Speech was hesitating, somewhat scanning, and the conversation was mainly carried on through his wife. His skin was moderately active, bowels rather constipated, urine alkaline with phosphates usually in excess, no albumen nor sugar, sp. gr. 1020. The pupillary reflex was slow, but equal in both eyes; all other reflexes were weak, slow or absent. Every action, mental or physical, was unusually slow.

No physical signs of any disease could be detected, and the diagnosis would have been promptly made of acute dementia or atonic melancholia, but no delusions of any kind were present.

The patient was given quinine and a general syphilitic and neurasthenic course of treatment, and recovered sufficiently to be able to resume charge of his business in six months.

There were no symptoms of progressive paresis, and the diagnosis of syphilis could not be confirmed. The author thinks this case belongs to a separate class of which it is a type.

Precautions Necessary in the Use of Pessaries.

Neugerbaner has collected 282 cases in which pessaries have been the cause of more or less grave lesions of the genital organs, including 23 perforations of the bladder, 20 of the rectum, 1 of both the bladder and rectum, 2 of the *cul-de-sac* of Douglas, 3 of penetration of the pessary into the pelvic connective tissue, 6 into the uterine cavity, 4 of introduction of the pessary into the bladder through a fistula, and a very large number of cases of para and peri metritis and even peritonitis and septicæmia, including 8 fatal cases, 8 cases of carcinoma of the vagina, and many cases of incarceration in which the pessary could be extracted only by surgical means.

In spite of this long and varied list of accidents the author by no means rejects the pessary from the gynecological armamentarium, but does insist that when the use of a pessary is decided upon great care shall be taken as to its form, size and the substance from which it is made, and that furthermore the patient shall subsequently be under the control of the physician. Neugerbaner himself generally uses globular or ovoid pessaries.

The author lays great stress on the point that the patient should exactly understand how to withdraw the pessary at night and insert it in the morning herself, and in cases of pessaries used for retro displacements the patient should be taught to withdraw the pessary herself on feeling the slightest pain from its presence, and not to be forced to wait until her physician can do it for her.—*Ex.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE.

A Clinical Study of the Effects of Inhalations of Chloroform and Ether Upon the Kidney.

Wunderlich (*Cent. f. Chir.*) has examined the urine of 100 cases of ether and chloroform narcosis. The urine was carefully examined before and after, both microscopically and chemically. The investigations give the following results:

1. In those cases in which albumin is already present the amount of albumin is markedly increased—that is, when ether is the anesthetic used.

2. Albumin is frequently seen after inhalations of chloroform and seldom when ether is used. The albuminuria usually disappears in from twenty-four to forty-eight hours.

3. When chloroform is used casts are frequently found in the urine, but seldom after ether. The course of the albumin and casts is, in the author's estimation, an ischemia of the kidney or an increase in the blood-pressure.

The author, in conclusion, says the so-called "ether nephritis" may be excluded from medical literature.

Fatal Peritonitis Following Orchitis Due to Mumps.

M. Hornus publishes the report of a case of double orchitis occurring in a soldier aged twenty-two during an epidemic of mumps. It was not due to gonorrhœa and there was no venereal infection. It came on with a few colic-like pains, followed by frequent movements of the bowels. Both testicles were equally affected. The temperature was 103.1° F. On the second day the patient developed peritonitis, of which he died in forty-eight hours. The autopsy showed that the testicles were transformed into collections of pus, with no trace of seminiferous tubules. The spermatic cords were bathed with pus, which continued beyond the inguinal canal. The intestinal coils were covered with purulent and fibrinous deposits. The remaining organs were normal.—*Gaz. hebd. de med. et de chir.*

Dangers of Internal Antiseptic Medication.

P. Dignat (*Jour. de Medecin de Paris*), in a timely article, writes of the dangers accruing from the internal administration of antiseptic remedies. He describes in detail two cases in which the ingestion, respectively, of salol and guaiacol, in comparatively feeble doses, produced a series of untoward symptoms. After a careful observation and study, these symptoms could only be ascribed to the action of the remedies alluded to. The author believes that antiseptic internal medication renders good service, but insists that the fact that such medication is apt to do more harm than good in many instances should not be lost sight of in modern therapeutics.

The Diuretic Action of Calomel.

Sklodowsky (*Deutsch. Archiv f. Klin. Med.*) affirms that as a diuretic calomel acts in renal disease better than in cardiac troubles. In seven out of fourteen cases of well-defined Bright's disease, accompanied with œdema, calomel was found superior to all other diuretics recommended to-day. In summing up his experience, the author believes that calomel acts as a powerful diuretic, facilitating the disappearance of œdema in kidney disease, with the important advantage that the drug does not produce noxious effects at all on the renal tissue. He believes that calomel ought to be tried where other diuretics have failed to act.

Chronic Constipation in Children.

Dr. Starr (*Hospitals-Tidende*), in the chronic constipation of children, a disease which is quite frequent, and where the ordinary remedies usually fail, has found the following suppositories of service:

Extr. belladonna.....	o	03	gr. ss
Aloes.....	o	60	grs. ix
Cacao butter.....	6	o	ʒjss

One or two a day, introduced in the rectum.

Pruritus of the Vulva.

Dr. Thomas More-Madden says in the *Medical Times and Hospital Gazette:* "Of the local sedatives that may be employed, none is more generally serviceable than a solution of methylene blue (which may also be given internally in pill form as a useful analgesic)."

For the same trouble the following formula is given by the *Medical Chronicle:*

Water.....	450.00 grms.
Alcohol.....	50.00 grms.
Mercuric chloride.....	1.00 grm.
Indigo-carmine.....	.05 grm.

M. Use as a lotion.

What Next?

"Vaccination" against diphtheria, as we suppose the process must be called until a name for it is invented, is now an accomplished fact, and the horse, it seems, is to be,

like the cow in relation to small-pox, the intermediary and modifier. See the wonderful wisdom of Providence: nothing is lost, nothing wasted. When tallow began to get scarce and dear coal oil was discovered. As timber in the older States thinned out and rails were rails, the barbed wire solved the fence problem. When the electric motor emancipated the horse and the patient mule from the street-car service, what to do with the horse became a problem, which the French solved by eating him. Behold! science has dedicated the emancipated animal to nobler uses and he is not yet *hors du combat;* he is to be used to knock out diphtheria —a kind of *equine*-knocks, eh?—*Ex.*

Clean Thermometers.

Those who are constantly preaching the germ causes of disease are the very fellows who many times are equally as careless as their unbelieving friends. How frequently do we see physicians take the temperature of their patients, regardless of the existing disease, wipe the instrument with their handkerchief, which is the most liable linen to be full of germs, or a towel or even use the sheet, and carefully place it away in a case preparde with a small amount of absorbent cotton in the bottom to keep from breaking, and unintentionally preserving the germs from time to time, to be conveyed to the next unfortunate, who may be the first patient called upon. This seems to be a very simple thing to discuss, but any reasonable person can readily see the necessity of having his thermometer thoroughly cleaned every time it is used. It should be washed with soap and water, and if any cotton is used in the bottom of your case let it be sublimated cotton and occasionally renew it.—*Charlotte Med. Jour.*

Syphilis.

M. Jullien states that a 25 per cent. mixture of calomel in liquor guttæ perchæ may be utilized in the treatment of syphilis, painting it upon a greater or less extent of skin three times a week. The mercury is absorbed, and this method is useful when the stomach is intolerant.—*La Tribune Medicale.*

Borax as an Aid to the Digestion of Milk.

Germaine See has recently announced the clinical fact that borax used internally is a valuable aid to the digestion of milk. He discards the use of carminatives, charcoal and other intestinal antiseptics, claiming that they injure the mucous membrane of the intestines. He employs laxatives—hydrastis canadensis, castor oil and olive oil—in large doses or oil enemata. Prof. See holds that in many cases of indigestion the stomach is erroneously treated when the real cause of the disease are the intestines, which are often the seat of membranous enteritis resulting from constipation, and giving rise to glary, mucilaginous, cylindrical masses of mucus, with pain and swelling over the region of the colon. These symptoms easily distinguished the cases referred to from ordinary constipation, in which there may be clearly seen masses of filamentous or vermicelli-like mucus.—*Modern Med.*

Blood-Letting in Eclampsia.

The *British Medical Journal*, in commenting upon Tarnier's recommendation of blood-letting in eclampsia, suggests that the simple withdrawal of a small amount of poisonous blood does not necessarily diminish the poisonous properties of the blood which remains; and since it is now well established that the symptoms of eclampsia are due to toxæmia, or general poisoning of the blood, it is evident that the most rational thing to be done is to diminish the amount of poison in the blood. How may this be done? A practical method has been the adoption of a milk diet for some weeks prior to the confinement. By this means the blood will be largely diluted; and if the eclampsia appears without premonitory symptoms, the blood may be diluted by making the patient drink copiously of water, by means of large salt-water enemata, and in extreme cases even by subcutaneous injection of a normal saline solution. The blood may be washed by adding to this such eliminative measures as will subtract the watery portion of the blood—as vigorous perspiration, purgation by means of the salines or even croton oil in extreme cases, and increase of kidney activity.

Elimination through the skin is the best of all the measures mentioned, through the bowels ranks next in value, and by way of the kidneys least available, owing to the fact that about the only way in which kidney activity can be stimulated directly, except by diluting the blood and thus increasing the blood pressure, is by means of diuretics which are in themselves more or less toxic. Faradism applied over the region of the kidneys and the solar plexus or abdominal sympathetic ganglia is a valuable means of stimulating renal activity. Blood-letting will probably seldom be required in eclampsia when the measures mentioned can be made available. A decided objection to blood-letting is the fact that not infrequently eclampsia occurs in patients who are already anæmic and exhausted by prolonged labor, so that a depletion of the blood is decidedly undesirable. One is never certain also, in cases of this sort, that the labor itself may not be followed by profuse hemorrhage, which, added to the depletion already effected by the blood-letting, might be fatal in its consequences, though insufficient to cause death by itself.

Acetanilide for Vomiting.

Among the many uses to which acetanilide has been put other than that of an analgesic, we desire to call attention to its employment in the treatment of obstinate vomiting, particularly when that vomiting seems to be due chiefly to nervous disturbance or marked

gastric irritability. In the treatment of the vomiting following operations acetanilide is particularly useful, and the administration of two grains every hour until six grains are taken will often prevent this unpleasant sequel of operative interference. We have used acetanilide for this purpose a number of times with very satisfactory results, our attention having first been called to it by Dr. Brown, of Sioux Falls, S. D., who told us that it was his custom in country practice to leave acetanilide with the nurse after the operation, with instructions to administer the drug should vomiting after recovery from the anæsthetic be an annoying symptom.

Whether it is of value in the treatment of the vomiting of pregnancy we do not know, but we would suggest its further trial. Probably the best way to administer it is to place the powdered drug in a little brandy, and then to add to a spoon some ice which has been finely pulverized. In this way we not only get the stimulating and antiemetic powers of the brandy, but we aid in the solution and therefore in the rapid absorption of the acetanilide. It is possible that the drug exercises its antiemetic effects chiefly by its influence upon the stomach itself, but we are inclined to think that the benefit is derived not only from this, but also from its influence on the nervous system after it is absorbed.—*Ther. Gaz.*

Treatment of Puerperal Eclampsia.

Dr. A. Charpentier (*Arch. de Soc. et de Gyn.*) gives a very extensive statistical review of the different methods of treating puerperal eclampsia in the various maternities of Paris and the method known as Duhrssen's. He arraigns the latter in very forcible language, characterizing it as brutal and unjustifiable. He sums up as follows:

1. Every pregnant woman with albuminuria being exposed to eclampsia should be put on an exclusively milk diet. This form of treatment serves as the best prophylactic of eclampsia.

2. Whenever one is called to a case of eclampsia and he finds that the patient is strong and vigorous and very much cyanosed, he should begin by withdrawing from four to five hundred grammes of blood by a venesection and then administer chloral either by mouth or *per rectum* as described in the text.

3 If the woman is delicate and the cyanosis but slight he should limit himself to the chloral medication.

4. Wait for the labor to come on spontaneously and do not interfere with the natural delivery whenever this course is possible.

5. If labor has set in spontaneously and delivery has not taken place on account of feeble uterine contractions, terminate labor by application of forceps or version if the child be living or by craniotomy if the child be dead.

6. Delay interference until the maternal parts are in a condition to render interference free from danger to the mother.

7. Reserve *accouchement provoque* for exceptional cases or when medical treatment has completety failed.

8. Reject absolutely Cæsarean section or *accouchement force* by deep incisions of the cervix, so to speak "the bloody method."

Medical Observations Among the Eskimos.

Dr. Frederick A. Cook (New York *Jour. of Gyn. and Obst.*), who was with Peary in North Greenland, observes that between the 74th and 79th parallels the Eskimos live on an absolute meat diet. Two-thirds of this meat is eaten raw and frozen and about one-third is cooked. For about ten months in the year they melt snow and ice for drinking-water; they use no salt or any condiment, nor do they ever bathe. They are fat and round, and the least excitement will cause blood to flow from their mucous membranes and a slight cut will bleed for an hour or two. The girls marry at twelve or fourteen and the men about ten years later, although girls do not menstruate until nineteen or twenty. Deaths in childbirth are not uncommon. During the whole of the long arctic night their secretions and passions are diminished and depressed, resulting in great muscular debility. Their women do not usually menstruate during this period, and the race are only passionate periodically—this period being that of the sun's return—when they fairly tremble with passion's intensity. During this period they have their courtship, and the few weeks of the sun's stay are mostly taken up in the active and most assiduous worship of Venus. Lactation lasts for from four to six years. Among the northern tribes there exist rheumatism and amygdalitis of the follicular type, also mild forms of the grip. Further south 50 per cent. have phthisis and the grip carries away its thousands.

The Treatment of Dysmenorrhœa.

Dr. Schwarze speaks with emphasis against the use of narcotics. Virburnum prunifolium, fluid extract, in teaspoonful doses thrice daily for from five to seven days before and continued during the menstruation, gives excellent results without unpleasant after-effects. It is not so successful if an inflammatory condition is associated with this symptom. He has noted also its value in arresting threatened abortion, even after the dilatation of the os uteri has been established. In many cases local massage is of great value, but it should only be employed in those which are not erotic. The use of a uterine sound before menstruation is followed by relief, and of still more value is dilatation of the entire cervical and uterine canal. Electricity —galvanic current, aluminium negative pole in the uterus, large positive pole upon the abdomen, current of from fifty to sixty milliamperes—has been of service in many cases. Castration is not indicated from the standpoint of the gynecologist alone, but only after consultation with the neurologist and alienist.—*Ther. Monat.*

SURGERY.

Imperforate Anus.

Henry Strachan, of Kingston, Jamaica, reports the following interesting case, which was under his care in the Kingston Hospital (*Brit. Med. Jour.*):

J. B., aged nine months, had never passed a stool, but the mother had noticed that fluid fecal material in small quantity passed away from the "front passage." There was never any "back passage." The infant had only begun to suffer during the past two or three weeks.

It was found that there was an imperforate anus. Deep pressure did not define the rectum, but a fistulous canal, just large enough to admit the passage of a small director, led from the fourchette, upward and backward, to what was evidently the blind end of the rectum. The abdomen was distended and evidently tender, but the general condition was not grave. I decided to operate from the anal site.

An incision was made in the pigmented spot of skin which occupied the usual position of an anus, and a careful dissection reached the end of the rectum, which was about an inch from the skin surface, without opening the peritoneal cavity. The gut was incised with scissors and the wall of the rectum brought down and stitched to the skin. An enormous evacuation of solid and semi-solid feces followed. The child made a rapid and perfect recovery.

The case is interesting as showing how long an infant could exist passing only a little fluid feces daily through a fistulous passage about the size of a crow-quill. It was only when the accumulation of gradually solidifying fecal matter began to extend the abdomen that any symptoms of obstruction manifested themselves, and this not until the child was nine months old. The rapid and complete recovery is satisfactory, for the mortality following this operation is usually high. Perhaps the greater age and development of the child at the time of operation placed it in a better situation for recovery than obtains in infants operated on when only a few hours or days old.

Dangers of Bicycling.

At a recent meeting of the Paris Academy of Medicine M. Hallopeau read a criticism on the article by M. L. H. Petit in which he reported three cases of sudden death from heart disease while bicycling. The opinion held by M. Petit that the exercise is contraindicated in old men and in persons with cardiac disease seems to M. Hallopeau to be exaggerated. He thinks that similar accidents, or those due to the bicycle alone, are so unusual that they are of secondary importance. In lung diseases he considers bicycling a useful respiratory gymnastics which increases notably the amplitude of the respiratory movements. His report terminated with conclusions which, after slight modifications, were adopted by the Academy, as follows: 1. The Academy recommends all persons who desire to indulge in bicycling to submit at once to a medical examination. 2. In experienced persons in good health the moderate use of this machine does not affect the cardiac functions. 3. The efforts made either when first learning to ride or with too rapid riding or by ascending of hills are, perhaps, to be looked upon as dangerous. 4. It is chiefly for heart and lung diseases that interdiction is perhaps absolute. 5. The Academy desires to receive articles from physicians throwing light upon this question.—*Gaz. des Hopitaux.*

Antiseptic Treatment of Gonorrhœa.

The great endeavor in modern therapeutics is to treat disease antiseptically. Gonorrhœa is a disease which in some cases will yield to any treatment and in other cases to none. It may occur from early childhood to late in life, and the first attack is usually the severest. It is a highly contagious disease and is usually self-limited.

The treatment varies very widely in different hands. Dr. Edward Pendleton advocates in the *International Medical Journal* this antiseptic treatment. After preliminary directions as to the methods of injecting the fluid, he says the penis should be washed in warm water and in a warm carbolic-acid solution (1 to 30), then a simple injection of water should follow. After the injection has been used for six days the following is recommended:

Acid. borici	ʒ ij
Tinct. iodi	ʒ ij
Glycerini	ʒ j
Aquæ	q. s. ad ʒ iv

M. Sig.: Inject three times daily.

If there is no discharge for ten days after the last pus is seen the patient may be considered well.

Vaccination.

Wm. N. Swift, of New Bedford, in discussing the technique of vaccination, lays down the following rules: Except in epidemics of small-pox, children should only be vaccinated when in good health. Cutaneous eruptions of all kinds are a contraindication. Vaccination should be done with the same care as any minor surgical operation. The skin should be carefully washed with soap and water. The vaccine lymph must be fresh, certainly not more than one week old. The virus should be inserted at more than one point. The point of inoculation should be kept perfectly clean throughout the whole course of the disease and protected from friction. The patient, meanwhile, should be considered as suffering from a mild disease.

As regards the improvement possible in this country, Samuel W. Abbott, of Wakefield, Mass., proposes the adoption of the

following general and special measures: 1. Cultivation and production of vaccine lymph by the United States Government for the use of the army, the navy and the marine-hospital service, and for all public institutions managed by the Government. Each State should produce its own lymph for the use of its public institutions and for the use of all local boards of health of cities and towns. 2. The abolition of agents and middlemen and the issuing of lymph directly from the producers to the parties who use it, every package to be stamped with the date of its collection. 3. The employment of better and more uniform methods of inoculating animals. 4. The exclusive use of animals less than one year old. 5. Limiting the time of collecting of lymph to a period of five days, or at the outside to six days, from the date of its insertion. 6. The adoption of careful rules for every establishment relative to cleanliness, the care of animals, etc. 7. If adult animals are used, a requirement that they shall be slaughtered before the lymph is issued.—*Boston Med. and Surg. Jour.*

Chronic Inflammation of the Seminal Vesicles.

Chronic inflammation of the seminal vesicles is not always easy to make out, as it has symptoms like inflammations of the urethra. Allen, in the *Medical News*, says that there may be a chronic urethral discharge with shreds in the urine or there may be vesical irritability with frequent micturition. In many cases there is some disturbance of the sexual function. In considering this subject the author offers the following suggestions:

1. The fluid in a distended vesicle, subjected to pressure, would escape at the point of least resistance, which would be the natural outlet, no matter how tortuous, unless the wall of the vesicle were ruptured by violence. Simple pressure on such a blind sac would seem better than an attempt to strip the vesicle down toward the duct.

2 The slow and unsatisfactory progress of a few cases may be due to the difficulty of emptying such portions of the vesicle which may in these cases be the chief seat of disease.

3. In some cases the ampulla of the vas deferens may alone be affected, when the stripping process would be easy and effective.

4. Disease of the vas deferens may possibly be of more importance than that of the vesicle itself, obstructing as it does the direct road from the testicle.

5. Simple massage of the vesicles may play an important part in the treatment.

Fixation in the Treatment of Fractures into Joints.

A paper with the above title was read before the American Orthopædic Association by Ansel G. Cook, M.D., of Hartford, Conn. (*Internat. Jour. of Surg.*), from which the following quotations are made:

All text-books on surgery that I have been able to consult assert or tacitly admit that fixation of an injured joint produces ankylosis. The same books also teach that broken bones should be set and kept in place till firm bony union has resulted. The question of passive motion is therefore a most difficult one to decide. If the surgeon moves the joint he disarranges the fragments of broken bone and hinders union; if he fails to make passive motion the joint becomes ankylosed.

Hamilton says passive motion should be inflicted as early as the seventh day after the injury; while Bryant says it should not begin until the end of the third or fourth week.

Conclusions and Rules of Treatment.—1. The bony or fibrous ankylosis is the result of injury and subsequent inflammation and not of immobilization.

2. That early passive motion only disarranges the fragments of bone, thereby increasing the production of callus; that it irritates the injured ligaments, and by increasing the inflammation tends to produce the ankylosis it is sought to prevent.

3. Immobilization is useful only when active inflammation is present or the ruptured ligaments and broken bones have united.

4. The logical treatment of a fracture into a joint, therefore, should be rest and local applications to reduce inflammation. Reduction of the fracture as early as possible, then immobilization until the bones and ligaments have united (from three to eight weeks or more, according to circumstances).

5. Passive motion and massage and use till the tissues become normal, or if the massage fails complete rupture of all adhesions under an anesthetic. The factors which will ultimately determine ankylosis are the nature of the original injury, the character and duration of the subsequent inflammation, the destruction of bone and cartilage, cicatricial contractions of the soft tissues around the joint, and the age and condition of the patient.

Abortive Treatment of Gonorrhœa by Permanganate of Potash.

Large injections of permanganate of potash methodically used is the best method of treatment yet introduced. Its advantages are: being absolutely painless in cases of anterior urethritis and scarcely painful in cases of inflammation of the whole tract; it can be commenced or left off without inconvenience; it has no detrimental action on the mucous membrane, but suppresses every trace of discharge from the first lavage, and is successful about eleven times out of fifteen. The size of the injection, its frequency and strength, must be adapted to individual cases. Generally strengths of 1 to 4,000, or 1 to 2,000, or even 1 to 1,000 are tolerated.—*Times and Register.*

Replantation.

The operation consists in replacing in its socket a tooth which has been partially or completely dislocated. The union after replantation is brought about through the periodontal membrane. In cases where the tooth is living and immediately replaced, a re-establishment of the vitality of the pulp is

sometimes produced. Magitot, who has recorded a large number of cases of replantation, maintains that, for success, there must be a complete ring of healthy membrane on the tooth. Results depend upon the nature of the conditions for which the operation is undertaken. If for traumatism and the tooth is immediately replaced, a permanent result may be looked for; but, on the other hand, if replacement is delayed the prognosis is naturally not so good.

Harrison (*Quart. Med. Jour.*) has had four such cases, and reports in detail an interesting case illustrating the above statements.

Influence of Sea Baths on Menstruation.

M. Houzel stated that most authors are in accord in the opinion that baths are contraindicated during the menstrual period. This opinion may be correct as regards the women of towns, but his personal observation has shown him that the robust and perfectly natural woman is not in a condition bordering on illness during this period (*Univ. Med. Mag.*). With her menstruation is a purely physiological act, silently accomplished and accommodating itself to the fatigues and vicissitudes which the necessities of life impose upon her. Sea baths, far from deranging, favor menstruation, prolong the period of sexual activity and increase her fruitfulness. He has frequently been surprised to see the fisherwomen, poorly nourished, slightly clad, feet and limbs bare, wade into the sea up to the waist, and sometimes up to the armpits, remaining there for hours. In spring and summer, having filled their nets with shell-fish, they come out of the water, and with their wet clothing and the dripping net on their shoulder traverse the town selling their fish. In the winter they may be seen, in coldest weather, with a heavy basket of mussels on their backs, from which the icy water constantly drops. Sometimes their clothes are completely frozen during menstruation, yet without causing any ill effects whatever. All this may seem surprising and may by many be attributed to race and habit, but a study of sea baths and their effect on the uterus easily explains it, and shows that all women, except those with grave lesions of the appendages, might imitate these fisherwomen to great advantage, provided they allow themselves time to receive the benefit of the sea air and to become accustomed to sea baths before going into the water during the menstrual period. Of 123 fisherwomen examined by Dr. Houzel puberty occurred on an average at the age of thirteen years and ten months, and the menopause at forty-nine years and six months—a difference in their favor, as regards the period of fecundity, of three years and seven months over women not going into the sea. According to Raciborski (" *Traite de la menstruation*," pp. 200, 248, *et seq.*) the average period of sexual life of the Parisian woman is thirty-one years and seven months.

Hæmatoma of Ovary.

Dr. Rohe does not agree with the view that this condition is due to excessive hemorrhage into the Graafian follicle after rupture and escape of the ovule. Sometimes hæmatoma exists when no rupture has taken place, and the corpora lutea frequently contain no blood. He thinks the view more rational that hæmatoma of the ovary is always to be regarded as a pathological formation having no connection with ovulation. He doubts whether any good purpose is served by the so-called "conservative" surgery, which consists in extirpating the hæmatoma, stitching up the wound in the ovary and dropping the organ back into the pelvis. Cases coming under his own observation have always presented either adhesions or displacements of the ovaries, and there are recognized indications for removal of the organs. Cites Dr. B. F. Black, "a careful and conservative gynecologist," in support of his views that ovaries affected with hæmatoma should be removed.

While admitting that the corpus luteum is an undoubted endothelial structure, Dr. Rohe thinks the statement of Dr. Foerster (*Am. Jour. Obst.*) that "what was previously called a corpus luteum is invariably an endothelioma" is open to grave doubt. Then he quotes Dr. Foerster's statement as to the connection of the corpora lutea with the production of hæmatoma. In his own view, hæmatoma is probably due to some nutritional change in the ovary or its blood-vessels, but what such change may be due to he leaves to the pathologists to determine.

Dr. Rohe goes on to describe a case which he thinks shows that there is no essential difference between so-called ovarian apoplexy, where the entire ovary is converted into a blood-cyst, varying in size from a billiard-ball to a fetal head, and those cases which present small collections of blood in the ovarian follicles and minute extravasations in the ovarian stroma.

An ovarian hæmatoma may rupture and give rise to pelvic hæmatocele; or bleeding may continue and patient die of hemorrhage. Peritonitis or sepsis is the most serious danger following rupture.

The diagnosis cannot be definitely made out before abdominal section, and the only rational proceeding is removal of the affected organ.—*George H. Rohe, M.D., in Amer. Jour. Obst.*

OBSTETRICS.

Intra-Uterine Injections in Antiquity.

At a recent meeting of an Edinburgh medical society Dr. Ballantyne quoted from a paper by Dr. Koromilas, a Greek physician, in which it was claimed that there was evidence in the writings of Hippocrates, Oribasius, Paulus Ægineta and Galen to show that these authors were acquainted with the use of intra-uterine injections. Hippocrates divided the degenerative organs into three parts—first, the external genitals; second, the genital organ or vagina; third, the uterus. He also used for each a special kind of substance to be injected; wine with honey for the external genitals, goose-grease for the vagina and oil with honey for the uterus. Dr. Koromilas believed that Hippocrates was the first to make intra-uterine injections.—*Med. Rec.*

Symphyseotomy.

The conclusions of Morisani, who has tested the operation perseveringly during twenty-eight years, were given at the recent congress in Rome and are of interest. He believes that clinical experience has fully justified the operation, and gives the limits of pelvic contraction in which it is indicated as 6.7 centimeters to 8.8 centimeters. The fetus should be alive and the operation performed at term, with dilatation advanced. At the present time he does not favor a combination of premature labor with symphyseotomy. The interpubic cartilage may be divided from below upward or from above downward, provided the subpubic ligament is surely divided. The subsequent use of forceps is useful, but not indispensable. To secure union in the joint it is sufficient to suture the soft parts and fix the pelvic bones with a bandage. He thinks the operation should only be compared with and is preferable to embryotomy when the fetus is alive, and predicts that it will take the place of the relative Cæsarean section. The supposed advantages of induced labor at the beginning of the ninth month over symphyseotomy at term are debatable. Ischio-pubiotomy, as done by its inventor, Farabeuf, differs from the pubiotomy of Aitkin and Galbiatti, and is a valuable operation in Naegle's obliquely contracted pelvis.

The alleged disastrous results of symphyseotomy are to be explained by the operation having been performed below the limit of its indication or at the wrong period of labor, by an improper manner of operating, by previous lesions of the genitals, or by special conditions of the patient. The death of the fetus must be attributed to too-long-delayed intervention, to faulty methods of extraction, or to accidental circumstadces.—*Internat. Med. Jour.*

Self-Infection in Childbed.

F. Ahlfeld, in a paper published in the *Zeit. f Geb. und Gyn.*, reaches the following conclusions:

1. The occurrence of fever in childbed, originating without previous examination, cannot longer be doubted.

2. The fevers for the most part are unimportant, though severe and even fatal cases are probable.

3. In well-conducted institutions the number of fever cases resulting from self-infection in childbed is larger than those caused by infection from without. The latter, however, are usually of a severer type.

4. The percentage of morbidity and mortality in an institution in which due care is taken to prevent infection from without depends on separating the primiparæ from the multiparæ and on the number of operative cases.

5. Preliminary disinfection of the birth canal is an important prophylactic measure.

6. Sublimate remains the best disinfectant.

7. The seat of infection is generally not the external genitals, but rather the cervix and endometrium.

8. Most fever cases in childbed are to be considered as resorption fever. They result principally from retention of the infectious childbed secretions.

9. The seat of the most active absorption is the uterine mucosa; next, that of the vagina.

10. The poison taken up is, as a rule, promptly eliminated—probably through the urine.

11. Pathogenic micro-organisms are always to be found in the vagina. They need only a favorable culture medium to develop their activity. This they find in the decomposing contents of the vagina and uterus after labor.

Danger of Intra-Uterine Injections of Glycerin for the Induction of Abortion.

Von Pfannenstiel (*Cent. f. Gynæk.*) says the results were such as to warrant a warning against further employment of the medium.

In the first case the woman succumbed to a nephritis from which she was suffering. In the bladder bloody urine was found, which condition was not present during life.

In the second case slight insensibility, cyanosis, fever to 39° C. and bloody staining of the urine, which was previously normal, occurred within an hour after the glycerin injection. The urine soon returned to normal. The microscopic examination showed hæmoglobinuria.

It is strange that other observers have never noted such an occurrence. But the second accurately studied and uncomplicated case speaks more than many positive cases. Hence this method must be forsaken.

GYNECOLOGY.

Senile Endometritis.

A. J. C. Skene (*Amer. Jour. of Obs.*) considers this condition quite different from the endometritis of early life. While in some cases it probably is a continuation of an inflammation which existed prior to the menopause, it is not so in the majority of cases. The disease may be limited to the cervical canal, but usually it includes the entire mucosa. It is as a rule suppurative, the discharge being sero-purulent, and when it begins as a catarrh it generally progresses to the suppurative form. The epithelium of the endometrium becomes almost entirely lost; granulations of low vitality spring up; minute extravasations of blood are seen with small pigment spots; atrophy of the muscular tissue was present and caused inversion of the mucous membrane; laceration of the cervix frequently existed; stenosis of the internal or external os was often present; pus would be discharged and again accumulate. When the disease had existed long enough to destroy the mucous membrane it might end in cicatrization, but it could scarcely be called self-limiting. Displacement, laceration of cervix, and a continuance of endometritis existing from early life are some of the causes of this attribute. Inattention to clean-

liness, also fibroma, may cause it. The treatment consists of the use of the douche of a solution of borax or sulphate of zinc if the inflammation is confined to the cervix. Medicated tampons, astringent and alterative applications, are helpful, but no caustics. Iodoform applied in the uterine cavity is very efficient, but its odor is objectionable. Complete closure must be overcome when it exists, and dilatation and drainage performed. Dilatation must be done gradually by graduated dilators. The complete removal of the uterus may be justified after other measures have been tried and failed, and when complete prolapsus exists vaginal hysterectomy is the proper treatment.

PATHOLOGY.

The Microbe of Mumps.

Our knowledge concerning this organism is both meager and uncertain. Various investigators have worked in this line, but their testimony is conflicting. Laveran punctured the parotid glands of patients suffering from mumps, and in the majority of cases a microbe having the form of a diplococcus was found.—*Modern Med.*

The Cause of Death in Extensive Burns of the Skin.

Kianicine has made some experiments to determine the presence of a ptomaine in the blood of animals affected with burns of large extent. In thirty-five experiments the ptomaines were found both in the blood and in the organs, while the blood of healthy animals, prepared in identically the same manner, did not contain this ptomaine. The method of Stas-Otto was employed in the same manner as is done by Brieger for preparing the pepto-toxine. Extraction is accomplished at a temperature of 80° C., with alcohol, evaporation, and the digestion of the remainder with a mylalcohol. Next, evaporation to dryness, dissolving the product in water, and purification by means of the subacetate of lead, by the use of sulphuretted hydrogen; and finally a purification by means of ether. This poison develops only in animals burned or scalded and is not a product of chemical manipulation. Some special reactions are given for it in the paper.—*Arch. de Med. exp. et d'Anat. patholog.*

ARMY AND NAVY.

CHANGES IN THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING NOVEMBER 30, 1894.

Murray, R. D., Surgeon; to proceed to Key West Quarantine and assume command of station, November 17, 1894.

Carter, H. A., Surgeon; to proceed to Norfolk, Va., and assume command of service, November 17, 1894. Granted leave of absence for fifteen days, November 20, 1894.

Wasdin, Eugene, P. A. Surgeon; to proceed to Pittsburg, Pa., and assume command of service, November 21, 1894.

Williams, L. L., P A. Surgeon; granted leave of absence for sixteen days, November 20, 1894.

Magruder, G. M., P. A. Surgeon; to proceed to Galveston, Texas, and assume command of service, November 21, 1894.

Kinyoun, J. J., P. A. Surgeon; granted leave of absence for six days, November 26, 1894.

Perry, T. B., P. A. Surgeon; granted leave of absence for thirty days, November 20, 1894.

Goodwin, H. T., P. A. Surgeon; to proceed to Cincinnati, Ohio, to inspect unserviceable property, November 20, 1894.

Guiteras, G. M., P. A. Surgeon; granted leave of abscence for ten days, November 28, 1894.

Geddings, H. D., P. A. Surgeon; to proceed to South Atlantic Quarantine and assume command of station, November 21, 1894.

Perry, J. C., P. A. Surgeon; granted leave of absence for thirty days, November 24, 1894.

Young, Y. B., P. A. Surgeon; granted leave of absence for ten days, November 20, 1894.

Strayer, Edgar, Assistant Surgeon; to proceed to Boston, Mass., for duty, November 22, 1894.

Blue, Rupert, Assistant Surgeon; to proceed to Charleston, S. C., for temporary duty, November 21, 1894.

Prochazka, Emil, Assistant Surgeon; leave of absence granted November 14, 1894, cancelled November 26, 1894.

Thomas, A. R., Assistant Surgeon; to rejoin station (St. Louis, Mo.), November 16, 1894.

Cumming, H. S., Assistant Surgeon; to proceed to Norfolk, Va., for temporary duty, November 22, 1894. Granted leave of absence for eighteen days, November 27, 1894.

NEWS AND MISCELLANY.

Important to Commercial Travelers.

On and after December 1st, Baggage Agents of the B. & O. R. R. Co. will accept coupons from mileage books issued by B. & O. R. R., P. & W. R'y, B. & O S. W. R'y and Valley R'y of Ohio, in payment for excess baggage charges, at their face value, 2 cents each. This arrangement will not include B. & O. Mileage Books indorsed "good only on B. & O.," B. & O. Southwestern Mileage Advertising Books, nor books older than one year from date of issue.—2t

Reduced Rates for Christmas and New Year's.

The B. & O. R. R. Co. announces that excursion tickets will be sold between all stations on its lines east of the Ohio River during Christmas and New Year holidays, at reduced rates, for all trains December 22, 23, 24, 25, 29, 30, 31, and January 1, 1895, valid for return passage until January 3, 1895, inclusive.—3t

THE
MEDICAL AND SURGICAL
REPORTER.

ORIGINAL ARTICLES.

FOREIGN BODIES IN THE EYEBALL, WITH REPORT OF CLINICAL CASES.

J. HOBART EGBERT,* A.M., M.D., PH.D., HOLYOKE, MASS.

Many penetrating wounds of the eyeball are accompanied by the lodgment of a foreign body within the interior of the globe. Foreign bodies within the eyeball give rise to most serious complications, frequently determining the loss of the wounded organ and tending to induce sympathetic inflammation in the uninjured eye. They may be of various characters—bits of steel, iron, stone, glass, shot and the like being commonly met with. Foreign bodies which do not involve the vitreous chamber or implicate the ciliary processes may usually be removed by proper surgical methods and the eye saved. A foreign body lying upon or imbedded in the iris may be removed by excising the portion of iris containing it (iridectomy); a body loose in the anterior chamber may be removed by paracentesis of the aqueous or by a pair of fine forceps introduced through a corneal incision; while a body lodged in the lens may be removed by extraction of the lens—which latter is sure to become cataractous or, in young persons, to undergo solution by virtue of the injury. Foreign bodies which penetrate the cornea and lodge in the iris are likely to occasion purulent inflammation of that membrane, which inflammation may become by extension a highly dangerous iridocyclitis. The following case gives extensive illustration of this class of injuries:

CASE I.—Mr. Alfred Christian, aged twenty-five, was the victim of a mine explosion early in the fall of 1892. Besides several more or less extensive bodily injuries, his eyes and upper portion of face were filled with small fragments of stone. He did not come under the writer's care until about three weeks after the accident. All foreign particles were first removed from the cornea, a foreign-body needle and spud being used for this purpose. These particles had already occasioned considerable corneal irritation and even ulceration. There was suppurative iritis in the right eye, which had poured out a quantity of pus into the anterior chamber. This was evacuated by paracentesis. The lens of the right eye was not involved. The cornea and sclerotica of the left eye also held numerous particles of stone; a single fragment was lodged in the superior external quadrant of the iris and another in the lens, which latter was displaced. As soon as the cornea of this eye had gained sufficient integrity an iridectomy was made, which served both to remove the particle of stone imbedded in the iris and as a measure preparatory to the extraction of the injured and dislocated lens. The iris of the right eye was destroyed by the traumatic purulent inflammation which, as already stated, was well advanced when the patient applied to us for treatment.

* Chief Surgeon Hampshire Eye and Ear Infirmary; formerly Dean St. Louis Ophthalmic and Aural Institute, St. Louis, Mo.; author "Enucleation of the Eyeball: When and How to Operate," etc.

During the entire course of treatment, with the exception of the last week, the patient was kept quietly in bed, while the strictest antiseptic precautions were at all times observed. The eyes were bathed every morning and evening with a weak, lukewarm bichloride solution (1 part to 8,000), and after each bathing a fresh dressing of five per cent. iodoform gauze, upon which a small quantity of boric-acid ointment was usually spread, was bound over them by a double bandage. When discharged from our care the patient had fair vision in both eyes.

Thus we see that even a number of small foreign bodies in and about the anterior chamber of the eye may, when properly treated, be recovered from with resulting good vision; but with the vitreous chamber and its surrounding tunics the conditions are changed. Whenever a foreign particle finds its way into the vitreous an exceedingly serious case is presented; while if the ciliary region of the eye has been implicated by the injury the severity of the case is still more increased. While it is certainly true that injuries of the eye are momentous in proportion as they affect the vision of the eye injured, still they are doubly so in proportion as they tend to produce sympathetic conditions in the uninjured eye. Wounds accompanied by the entrance of a foreign body within the eyeball not only frequently destroy vision, but are prone to induce sympathetic ophthalmia; nevertheless, under certain favorable conditions these bodies may be removed, the eye saved and serious sympathetic conditions avoided.

The body entering the eye from before pierces the cornea or sclerotica, and passing through the lens or tunics beneath the sclerotica, may traverse the vitreous and lodge itself in the fundus of the eyeball; or, as is sometimes the case, having spent its force it falls to the floor of the vitreous chamber, perhaps rebounding from the posterior wall. The first consideration is as to whether the body can be seen, and the second whether or not it is of steel or iron and therefore magnetic. The ophthalmoscope is applied to the locating of these bodies, but as profuse hemorrhage often attends their entrance, the chambers of the eye are not infrequently filled with blood, so that the fundus cannot be properly examined. Under these circumstances, if there are no symptoms of inflammation, it is allowable to keep the patient quietly in bed for a few days to see if the blood will not be absorbed and thus permit an examination of the fundus and possible location of the body by means of the ophthalmoscope. In all such cases, however, the patient must be carefully watched by the surgeon, who must hold himself in readiness either to search for the body or to enucleate the eyeball as soon as inflammatory symptoms present themselves, manifested by pain, marked tenderness over the ciliary region and softening of the globe. When these conditions are present, if the body cannot be found and removed by an exploratory operation, the injured organ should be at once removed and sympathetic ophthalmia thus avoided. The writer is not aware of any authenticated case in which sympathetic ophthalmia ever attacked an eye after its injured companion had been removed—the uninjured eye being unaffected at the time of the removal of the other. Moreover, sympathetic *irritation* usually disappears upon enucleation of the offending member; but if the disease has once fairly broken out, the prognosis of sympathetic ophthalmia from any cause is most unfavorable, and even the immediate excision of the eye primarily affected at this stage of the trouble generally fails to have any, or only a temporary, beneficial effect. Realizing the ominous import of sympathetic ophthalmia, the surgeon, as well as the patient, should be ever watchful for its well-marked approach and proceed at once to active measures as soon as its dangers threaten.

A word concerning the methods now employed for removing foreign bodies from the vitreous chamber. For the removal of steel and other magnetic particles a specially designed magnet is the most useful appliance: the forceps, grooved hook and similar instruments have been employed but with doubtful success, and generally speaking the eye which incloses a foreign body is usually doomed. Still, a few cases of the successful removal of foreign particles from the vitreous, with restoration of vision, are recorded. Very rarely invading particles have become encapsulated and remained quiescent during long periods of time, but even in these cases they may be expected to ultimately occasion secondary

inflammation. Wolfe reported a case in the *Medical Times and Gazette*, January, 1876, of a minute particle of iron that had been struck off from a nail and entering the eyeball remained lodged in its tunics, close to the optic nerve, for almost eight years. The eye gradually became blind, but the foreign body remained quiescent for the length of time mentioned and then suddenly caused great irritation in the other eye. The injured eye was thereupon promptly removed and the irritation ceased.

The following cases illustrative of the general course and treatment of these conditions cannot fail to prove of interest:

Case II.—On Wednesday, April 11th, a man thirty-five years of age applied at the hospital for treatment and gave the following brief history: A few hours before he had been cutting a heavy plate of metal with a chisel and hammer, when a bit of steel from the edge of the chisel flew off, striking him in the left eye. Upon examination of the eye it was found that the particle had passed through the sclerotica, just without the ciliary region on the temporal side, and thus entered the vitreous. There was sufficient blood in the eye to prevent examination of the fundus and location of the foreign body by means of the ophthalmoscope, and it was resolved to wait a short time to see if the blood would not soon be sufficiently absorbed to render possible an illumination of the fundus. Friday night, however—two days and a half after his admission to the hospital—pain was experienced in the eye; it presented a cloudy appearance and incipient inflammation was plainly announced. The fact that active measures must now be employed was communicated to the patient, and he was told that an attempt would be at once made to remove the offending particle, providing he would give his consent to having the eye removed in the course of the same operation if the body could not be found or successfully removed. He accepted the proposition and the following afternoon the operation was performed. The patient was etherized, the lids held apart by a speculum, and the opening made through the tunics of the eye by the entrance of the foreign body was dilated. A magnet devised by us for this purpose was now introduced through the opening and thrust about in the vitreous. This was repeated three times without removing the piece of steel. As a final trial the magnet was introduced but a short distance and made to sweep about the inner portion of the opening in the globe, and when withdrawn it brought with it the piece of steel, which had evidently been brushed off by the lips of the wound upon a previous withdrawal. Antiseptic precautions were, of course, rigidly observed throughout the operation. The opening in the sclerotica was united by means of a fine silk suture and the eye dressed antiseptically. The conditions began at once to improve. Before operation vision was reduced to perception of light; five hours after operation, $V=\frac{2}{200}$; forty-eight hours afterward, $V=\frac{5}{200}$; and at the end of the first week, $V=\frac{20}{200}$. After that the sight steadily improved and in due time the patient was discharged from the hospital with good sight in both eyes. It is true that the ultimate result of such cases cannot be foreseen, for eyes which have been thus injured by accident and operation are quite like those eyes which contain latent foreign bodies, in that they may some day cause trouble, even though it be years after the receipt of the injury.

The following case, while less fortunate in its results than the preceding one, presents only too truly the general outcome of the class of injuries we are considering:

Case III.—Saturday morning, August 13, 1892, a young machinist's apprentice, twenty-two years of age, was boring with a fine drill a piece of steel, when the drill broke and threw a small fragment of itself into the right eye of the operator. The drill was revolving at a high speed when the fracture occurred, and the fragment was hurled with considerable force. The patient came under the writer's observation about 2 P.M. the same day. Simple inspection showed that the particle of steel had pierced the eyeball just within the sclero-corneal junction in the lower segment of cornea and had passed, evidently revolving the while, through the outer tunics of the eyeball, through the iris and through the margin of the lens. The ophthalmoscope revealed a clot of blood in the posterior chamber resulting from the wound in the iris, and a haziness of vitreous caused by blood in the vicinity of the optic disk. The body could not be seen. The prognosis for the eye was most unfa-

vorable. The patient was put to bed and enjoined to lie quietly on his back to await developments. During the afternoon and evening there was no considerable pain in the eye, but the next morning pain began and the following evening was constant and intense, showing that inflammation was imminent and enucleation of the wounded eyeball the only issue. On account of the severity of the pain the patient did not greatly object to the operation, and early Monday morning—less than forty-eight hours after the receipt of the injury—the wounded eyeball was removed and the bit of steel found, not in the vitreous chamber, but imbedded in the tissues of the orbit behind the globe.

Foreign bodies which have entered the vitreous chamber are thus seen to be exceedingly portentous, not only frequently causing sightless eyes, but tending to induce sympathetic ophthalmia; and these accidents have furnished and will still furnish numerous eyes for enucleation.

PUERPERAL PHLEBITIS.*

BARTON COOKE HIRST, M.D., PHILADELPHIA.

Of all the forms that sepsis can present in a woman after labor, phlebitis, I should say from experience in consulting practice, is least understood, most often mistaken for something else and most frequently maltreated by the general physician. And yet there is no form of sepsis that has so many distinctive and peculiar characteristics if they are known and looked for. The most misleading features in the disease, from a diagnostic point of view, are the late appearance of symptoms and the entire absence of local physical signs of inflammation. I have known a septic phlebitis develop as late as five weeks after labor, and in all cases uncomplicated by other forms of septic inflammation the womb involutes well, is freely movable and insensitive; the broad ligaments with the uterine adnexa are apparently normal, while the general symptoms of high fever, rapid pulse, profound prostration and metastatic developments may be most marked. It is this absence of local symptoms that strengthens the indisposition in us all to admit sepsis as the cause of disease in our patients after childbirth.

Symptoms.—A typical clinical picture of puerperal phlebitis presents the following characteristics: Evidence of disease appears ten days or more after confinement; there may have been a slight evening rise of temperature from the beginning of the puerperium, and during this time the patient may have appeared somewhat restless or anxious with a flush on one or both cheeks; the pulse also may have been somewhat accelerated, but there is scarcely enough in the woman's condition to attract her physician's attention. After a varying but considerable length of time, with the premonitory symptoms just described or with none at all, the temperature rises high in twenty-four or forty-eight hours, a chill sometimes but not usually preceding the fever. The pulse is rapid out of all proportion to the temperature, there is a dusky flush on the cheek or cheeks and patches of red may appear on other parts of the body, particularly on the chest. The tongue is very foul. The patient has an anxious, troubled, restless look, but if questioned may reply that she feels perfectly comfortable, or if she feels ill she cannot complain of any localized pain or discomfort. The abdomen is not distended nor is it usually at all sensitive to pressure. A vaginal examination is entirely negative. The disease once begun runs a most tedious course. I have attended two patients who were seriously ill, with high fever for four months, and I think the woman lucky whose illness is not protracted beyond three weeks. Another most distinctive feature in the course of the disease is the tendency to complete remission of the fever and of all other symptoms for more than a week perhaps; then there is a recurrence of high fever, rapid pulse and profound prostration—in short, a reappearance of all the old symptoms in their original intensity, but the relapse does not often last long. I have seen such a

*Read before the Philadelphia Obstetrical Society.

relapse recur three times in an individual who had been ill three months before the first remission.

Complications.—As is well known, the commonest complication of phlebitis is phlegmasia, but the latter is by no means a necessary consequence of the former. I have seen many a case run its course without a swelling in the leg or legs and a number of cases besides in which the phlegmasia was a transitory, scarcely noticeable phenomenon in the course of the disease. Phlegmasia is too large a subject to consider here, and I shall simply refer to some interesting features of it that have struck me in my own experience. I have the notes of sixteen cases seen in private, consulting and hospital practice. In two instances there was double phlegmasia. In one case the swelling first appeared seven weeks after childbirth. In two cases there was a combination of the cellulitic and of the thrombotic phlegmasia. In one case there was an abscess in the popliteal space; in another, in the calf of the leg. In several cases the phlegmasia began as a pure pressure thrombosis, but in all these cases the clot eventually became infected and there was some septic fever.

It is a fact not generally appreciated that the thrombosis of phlebitis in the puerperium is not necessarily confined to the veins of the pelvis and to those of the lower extremities. Large veins far distant from the seat of original infection may be affected. As an illustration, my friend Dr. Fussell has told me of a woman under his charge in whom the longitudinal sinus of the brain was found solidly blocked by a well-organized antemortem clot. She died four weeks after confinement, death being preceded by coma and convulsions.

Another well-known complication of septic phlebitis is a metastatic septic inflammation anywhere in the body. The brain, the eyeballs, the lungs, the pleura, the kidneys, the liver, the spleen, the subcutaneous connective tissue may be the seat of an abscess. I have seen in a puerpera the whole of one leg and a forearm riddled by the multiple abscesses of suppurative cellulitis.

Still another complication is profuse hemorrhage from the veins of the placental site. One of my students has recently told me of a case in which there were repeated alarming floodings in the course of a puerperal phlebitis, following attempts at intra-uterine disinfection.

Treatment.—The treatment of puerperal phlebitis is summed up in a short sentence: Abstention from local interference and the freest possible use of stimulants and food. Any attempt at intra-uterine disinfection will make the patient distinctly worse. There is imminent danger of causing metastases or hemorrhage by local interference. In one of my patients an intra-uterine douche was followed by a chill, and within twenty-four hours by suppurative pleurisy. In another the temperature rose to 106.8° after cleansing the uterine cavity. This indeed is a diagnostic feature of considerable value, and is occasionally the only way to distinguish between sapræmia and phlebitis, as the following clinical history proves: I saw in consultation a lady who had been delivered three weeks before. She had had a temperature of about 103° for two weeks; her pulse was rapid; there was profound prostration, and one of the most distinguished physical diagnosticians of Philadelphia had the day before detected an incipient septic pneumonia. The abdomen was flat and not tender. The uterus was well involuted and perfectly movable. There was a slight bloody discharge without odor. All this looked very much like phlebitis. I thoroughly disinfected the uterine cavity, however, and within twelve hours the temperature fell to normal, the signs of pneumonia disappeared and the patient made an uncomplicated recovery. Had this case been one of phlebitis, as it seemed to be, my local interference would have made the woman much worse. But in spite of this risk I always carry out one thorough disinfection of the womb, even in a case in which I feel pretty certain of the diagnosis of phlebitis. The clinical history just related is sufficient for such a rule of practice. Having established the diagnosis of phlebitis and having shown the futility of local disinfection, my routine treatment is as follows:

Milk, predigested if necessary, and predigested beef at regular intervals and in as great quantities as the patient can digest; whisky, as near a pint a day as she can stand; or, if necessary, champagne in larger quantities. Digitalis for the rapid pulse and quinine and iron by the bowel.

The patient is kept in bed for at least ten days after all symptoms disappear.

Prognosis.—In spite of alarming symptoms and long continuance, the disease should end in recovery in the vast majority of cases. I have only lost one of my cases of phlegmasia and two other cases of phlebitis, a mortality of about 10 per cent. Among the women who recovered were some as desperately ill as I ever saw, so that I approach a case of this kind with considerable confidence as to the result.

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., NEW YORK.

[CONTINUED FROM PAGE 824.]

TREATMENT—*continued.*

Michaux severely condemns exploratory incisions until the time arrives when symptoms of serious internal trouble are present. This is usually within twenty-four hours after the injury, but it is often a difficult matter to correctly determine (*Gaz. Fev.*, Mai Avril 12, 1892). Up to 1893 there were but 7 cases on record, according to this author, in which laparotomy had been performed successfully for rupture of the intestine following contusion of the abdomen; one each by Moty (*Bull. de la Soc. de Chir.*, January, 1890, No. 1, p. 48), Croft (Chir. Soc., London, March 14, 1890), Taboda (*Wien. kl. Woch.*, 1891, No. 45, p. 837), Michaux (*Bull. de la Soc. Chir.*, January 27, 1892), Ch. Nelaton (*Buil. de la Soc. Chir.*, October, 1892), Michaux (*Bull. et Mem. de la Soc. Chir.*, 1893), Bouffin (*Congrès Francais de Chirurgie*, 1893).

CONTUSION DE L'ABDOMEN INDICATIONS OPERATOIRE.

Moty, when reporting a case of mortal contusion of the abdomen in a boy who was kicked by a horse, comments on the many difficulties attendant on diagnosis in abdominal injuries. He declares that the proper course of conduct in this class of cases is not yet definitely determined, though the general rule at present which obtains among surgeons is to laparotomize when there are good grounds for suspecting intestinal perforation; but he nevertheless maintains that "when we are in doubt an exploratory incision is not permissible and the expectant or medical treatment should be the rule."

Mr. Stanley has reported two serious cases of abdominal injury, one recovering and one dying. No operation (27th vol. *Med.-Chirurg. Trans.*).

Chavasse collected 149 cases and noted that mortality in conservative treatment was about 30 per cent. ("*Contusion de l'Abdomen*," *Memoirs de l'Acad. de Med.*, January, 1872). In McKenzie's 111 cases with tentative measures the mortality was 6 per cent. In one of them the stomach was ruptured and in another was rupture of the spleen (*Med. Trans.*, vol. xiii, p. 207).

Krause, at the Anatomical Society of Paris, presented the report of a case of violence to the abdomen of a man in which the question of laparotomy had been raised. Patient died in eighteen hours, and on post-mortem examination it was found that the duodenum was ruptured and the abdomen badly contused. Dr. W. B. Corson (*Jour. Am. Med. Ass'n*, November 5, 1887) published the case of a boy who had been kicked on the abdomen by a horse. He was seen ten days later, when he was moribund. On autopsy a rupture of the ileum was discovered, with free escape of its contents into the peritoneal cavity. This author favored early incision when patient could safely bear it.

The same author cited Dr. J. Gregory's case of a boy who fell but four feet, striking his abdomen on the edge of a ladder. In six hours death followed. An extensive rupture of the ileum was found near the cæcal junction.

Joubert ("*Traité de Maladies Chirurgicales du Canal Intestinal*") while dwelling

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

on this topic says that direct compressive force against the vertebral bodies is the preponderating cause of intestinal rupture; and adds that the repair of such an opening is very frequently satisfactory and prompt by atresia of the damaged wall to its healthy neighbor.

Tillaux, while a strong advocate of abdominal section in appropriate cases, nevertheless dwells with considerable fullness on the remarkable tendency of the peritoneum to take on adhesive inflammation. He would immobilize the intestine and administer opium with a free hand.

Mr. Edmund Owen, in "St. Mary's Hospital Reports," gives an interesting summary of the case of a man who was injured by a fall on the abdomen. Was seen by him the morning after injury. He had peritonitis and symptoms of a ruptured intestine, but was in shock when seen. On the following day symptoms were aggravated. Now, with patient's concurrence, abdomen was opened and a large rent in the intestine found within six inches of the head of the colon. Patient rallied fairly well but sank about six hours after operation. Mr. Owen thought that an earlier section might have saved his life, and concludes that in cases of an extensive rupture of the bowel death is sure to result, while a timely operation offers the only hope of saving life.

In a considerable number of grave injuries of the abdomen, symptoms of intestinal extravasation occur only as secondary phenomena. The intestine has been severely contused, or perhaps only a limited area of its wall; gangrene or ulceration follows any time from three to ten days, and a fulminant type of peritonitis follows.

Probably in this class of cases when primary shock has been survived the best prospects of good results follow laparotomy. Judging from the accumulated reports of laparotomies necessitated by abdominal contusions, it must be admitted that the prospects of success following them are very discouraging, and that the cases which demand them are so depressed from a general collapse or a sinking of the vital powers that a major operation is generally succeeded by a fatal termination.

As may be conceived, the mechanical therapy of visceral traumatisms within the abdomen is not always very difficult. But the great impediments to its success are the terrible tendency to additional shock after the peritoneum is opened and the imperative necessity for celerity of manipulation. Besides, notwithstanding what may be said to be contrary, peritonitis invariably follows every time the cavity of this sensitive serous membrane is opened, constituting in itself a fresh element of danger to life.

We have it on the most unimpeachable testimony that alarming symptoms may follow an abdominal contusion without any palpable pathological changes whatever. In a case of this kind would it not be a calamitous step to open the abdomen in search of a phantom—perhaps kill our patient outright through fresh shock or light up a fatal peritonitis?

But laparotomy, serious as it must be viewed, in cases of abdominal contusions associated with intestinal rupture which have survived shock and in which its indications are clear, offers the only hope of preserving life and should be recommended. Let no tyro, however, undertake it. Better thousand times to leave the case to nature; for this operation to succeed at all requires special skill and experience, a most thorough preparation of the patient and his surroundings, attention to detail and intelligent after-treatment.

The latest which has come into my hands on the discussion of abdominal contusions is from the Surgical Society of Nancy. It appears in the form of an essay and discussion which are so pertinent and interesting that nearly a full transcription of it seems warranted.

Vautrin began by affirming that "neither the violence of a traumatism, nor the shock following the first few hours after injury, nor the appearance of rapidly developing peritonitis, enabled us to diagnose with certainty rupture of the intestine in abdominal contusions." He further added that "when there were indications pointing to intestinal rupture there was no symptom which pointed to the part of the alimentary canal involved." As a rule, peritonitis only made its appearance after an interval of calm after primary shock had passed off. He would advise that immediately after injury, when there were reliable indications of intestinal rupture, the abdomen should be opened and an exploration made. For,

properly performed, he thought it would not augment the risks; and besides, if any benefit were to follow operation it must be now or not at all.

He had recently observed two cases. One was a man 40 years old, a teamster, who had been violently crushed in the right flank. Some hours after injury he was brought to the hospital and seen by Vautrin. Laparotomy was performed. Next day general peritonitis was well marked; there was great pain, intense thirst, exhaustion and fæculent vomiting. By autopsy a rupture of the small intestine was discovered midway between the pylorus and the cæcum. Besides, there was a slight laceration of the right lobe of the liver. The peritoneal cavity was filled with blood and intestinal contents.

The second case was a young man of 23 who fell 3 meters from a ladder. He was seen the day following injury. There was then ballooning of the abdomen, but no severe pain except over the umbilicus. Slight nausea and retching; pulse 125, but regular; temperature 36 5° C. The next day he remained about the same, but abdominal meteorism was increased. Laparotomy was proposed, but the family refused. The same night alarming symptoms set in and he died at three in the morning. An autopsy was denied.

From these two unfortunate cases and other observations Vautrin believed that surgical intervention was rather to be preferred than expectation. It was true that a great risk was entailed when one operated under shock, yet he alleged that it offered the injured the only hope.

M. Weiss, in the discussion which followed, declared himself a partisan of early operation when anything like definite indications were present; still he alleged that diagnosis was attended with difficulty. He cited the case of a young woman who had been kicked by a horse, in whom it was at first supposed the intestine was wounded, but who after a few days' rest made a good recovery.

Regnier cited the case of a cannoneer who was accidentally crushed over the abdomen. He saw him 24 hours after the injury. At this time the pulse was small, the face pale and the abdomen flat. Internal hemorrhage was diagnosed. The patient refused operation and died on the third day. On autopsy an extensive laceration of the liver was found.

M. Heydenreich agreed that when we were assured that there was intestinal laceration of considerable extent laparotomy should be resorted to. But we are usually in ignorance of this until it is too late to interfere. Two cases of serious abdominal contusion had come under his care. In one a man of 40 years had been kicked by a horse. Peritonitis promptly followed and he sank on the second day. A post-mortem examination showed an extensive rupture of the small intestine. In another case a man of 44 years had sustained two kicks from a horse over the abdomen. A fulminant type of peritonitis followed, but after the fourth day it began to decline and he ultimately made a good recovery. He believed that it should be more generally known that laparotomy itself is attended with about 25 per cent. mortality under any circumstances. In these cases it greatly augmented the danger to life and few survived it. It was temerity to open the abdomen in all, and was not justifiable in any but rare instances.

M. Froelich declared that it all depended on the degree of peritoneal shock present what course one should pursue. He had seen Professor Goltz, at Strasbourg, instantly kill a large dog by a blow on the abdomen which left no trace of lesion discernible on post-mortem examination.

M. Gross (*Rev. de Chirurg.*, September, 1894) communicated six observations for contusion of the abdomen, with the following brief recapitulation.

First case. A young man was thrown from a carriage, the wheels passing over the umbilical region. Alarming symptoms on the first day; menaced by peritonitis for four days; amelioration commenced on the fifth day and recovery was complete in one month.

Second case. A youth of seventeen years fell from a loft, striking on the wheel of a carriage. Peritonitis. Death on the fourth day. No autopsy.

Third case. A man of thirty-two kicked by a horse over the liver. Symptoms of hepatic injury with acute peritonitis. He sank after two months' illness. On autopsy suppuration of the liver was found, with gangrene of the small intestine near the jejunum and complete obliteration of the superior mesenteric artery.

Fourth case. A man of sixty-two fell

on an iron arcade. Subacute peritonitis. Laparotomy twenty-four hours after injury. Blood and fæculant matter in the peritoneal cavity. Suture of ruptured intestine; closure of the peritoneum. Death in twelve hours.

Fifth case. A young man of eighteen fell and was run over by a carriage. Threatened peritonitis for fifteen hours. Rapid recovery.

Sixth case. A woman of thirty years knocked down by a runaway and crushed over the abdomen. Menaced by peritonitis for thirty-six hours. Return of symptoms on third day with symptoms of intestinal obstruction. Died on the fourth day. On autopsy intraperitoneal hernia with strangulation was found.

M. Gross summarizes these cases as follows:

There were four deaths. The great factor which adds to the gravity of complicated abdominal crushes is the visceral complication.

First. Operative medicine judiciously applied must be our main reliance in all severe cases.

Second. To derive any benefit from operation it must be instituted early.

Third. Unhappily, an accurate diagnosis is not always possible. The surgeon must often delay until the time is past for surgical relief.

Fourth. In doubtful cases it is better to delay than venture a lapårotomy.

INTRAPERITONEAL HEMORRHAGE.

In cases of sudden exsanguination from intraperitoneal hemorrhage from abdominal crushing, should the peritoneal cavity be opened and its source sought for? On superficial reasoning one might say, Certainly; why not?

The late Dr. Chas. F. Parkes and others believed that by opening the peritoneum and admitting the atmosphere it favored the arrest of hemorrhage. But this is clearly an error, for such is not the case. When we appreciate the fact that great hemorrhage comes from the laceration of a solid viscus or the opening of a large blood-trunk, in which case to interfere is to destroy life; that the serous secretion of the peritoneum is alkaline and favors coagulation of the blood; that the source of hemorrhage is equally but firmly compressed on all sides, the degree of pressure being the greater the larger the escape, then it is more apparent that a laparotomy adds new dangers and interferes with nature's means of subduing bleeding. The utter futility of attempting to subdue the intra-abdominal hemorrhage when large trunks within the abdomen are opened was recently illustrated in the case of the assassination of M. Carnot, when MM. Ollier and Poucet in vain tried to stem the tide which was springing from the cava, portal vein and hepatic artery.

Two cases of very large intra-abdominal hemorrhage came under my care last May (1894), one from a gunshot and one from a crush. Both were laparotomized. The blood torrent which issued through the incision in both when the peritoneum was opened was awful and could not be controlled. Both died on the operating-table. One, who had a ruptured spleen, might have been saved had he been treated on the expectant plan. Both, I am positive, would have survived much longer had they been left alone. When an opening is made and the blood is allowed to escape outward the loss or waste is irretrievable. But when pure aseptic blood is taken back into the economy there is a great gain. My experience and knowledge gained from a fairly practical acquaintance with these cases convince me that a laparotomy is not to be recommended in any type of hemorrhage succeeding abdominal contusion; that the chances of the patient are much enhanced by local and constitutional measures which do not imperil life.

INJURIES IN THE HYPOGASTRIUM AND INGUINAL REGIONS—VESICAL RUPTURE AND TRAUMATIC HERNIA: THEIR TREATMENT.

If the wall of the bladder be ruptured in the space of Retzius, the infiltrate into the cellular tissues will probably undergo resorption and the rent close of itself. But when the opening is through the fundus and penetrates the peritoneal coat, the danger of peritonitis is great and a laparotomy may be required to close in the breach.

Sir Wm. McCormick cites 16 cases of intraperitoneal rupture of the bladder from traumatisms. Six were operated on and saved ("Encyclop. Surg.," vol. vi., p. 327).

Mr. Reginald Harrison says that "when rupture of the bladder has extended into the peritoneal cavity, I can find no evidence to warrant the belief that life has ever been saved without surgical operation. When life has been saved it has been due to the aid of the surgeon" (*ibid.*, p. 327).

But vesical wounds heal with surprising rapidity, and I am not sure but the latter author has rather exaggerated the dangers of temporizing. My own practice would be to catheterize with great caution and watch for the onset of serious symptoms before instituting radical measures. The intestines fall snugly over the wall of the bladder; they may quickly become adherent to it and effectually confine the urine. The bladder being kept empty, no tension is placed on its wall and union is favored. Boracic or benzoic acid may be freely given by the mouth for their sedative and healing effects on the vesical mucous membrane.

If, however, there be great and constant pain in the hypogastrium, with marked constitutional irritation and vesical tenesmus, our diagnosis is positive and we may consider the propriety of a laparotomy, but not otherwise.

TRAUMATIC RUPTURES (HERNIÆ).

Guthrie, Pirrie and other authors allege that atrophic changes often occur in the muscles of the abdominal walls after contusive violence over any part of them. If this allegation can be supported, then it behooves us to endeavor to prevent such changes or modify their effects by appropriate treatment. In a considerable number of abdominal injuries which have come under my observation, no such sequelæ have been noted; nor can I find any mention of them in the works of many of the most celebrated authorities.

Kicks or crushes over the inguinal planes which are devoid of a complete muscular investment, one might assume might provoke such an extensive rupture of the aponeurotic fibers as would permit the intestine to slip through. It would seem reasonable to believe also that great compressive force over the parietes might so displace the viscera underneath that they would engage in or pass through the canals of emergence.

Aponeurotic fibrous structures, however, probably are as resistant to force as are the muscular, and hence are never extensively rent except when the organs invested by them are seriously damaged. We will sometimes have a patient who has an old hernia tell us that it was caused by a blow or fall in early life; at least, that he was not aware of its presence until after this event. In these instances the weight of opinion is that the evolution of the hernia was probably but a coincidence, or at most that a predisposition existed and the traumatism was but an exciting cause. There is no direct proof that local contusions over the abdomen will provoke hernia. Compression over the abdomen *en masse* certainly will not, as several cases which have come under my care demonstrate; such cases as result from buffer crushes, those cases in which heavily loaded vehicles have passed over the abdomen, and those in which the patient in a fall has struck with great force on the abdomen.

But if such injuries cannot be said to directly cause herniæ, they certainly do leave the contused over-strained muscles weak; so that when one rises he feels a dragging sensation in the back, the lax abdominal walls permitting of a sagging of the floating viscera and an undue tension of the mesentery which has its anchorage over the bodies of the lumbar vertebræ.

Now, a girth or broad belt will give great support and afford much comfort. It should be worn until tone is restored to the abdominal muscles, till their nutrition is improved and their functional vigor is regained. Heavy lifting and violent exercise should be eschewed for a considerable period; for a structure once seriously damaged on violent abuse is certain to manifest a diminished resistance.

COMMUNICATIONS.

ACCIDENTAL AND CONCEALED HEMORRHAGE, WITH REPORT OF A CASE.

JOHN STROBEL, PH.G., M.D., PHILADELPHIA.

The so-called accidental hemorrhage, or that which occurs from premature detachment of the normally situated placenta, is not frequent and especially its grave form is rare. The hemorrhage may be open or concealed, or both forms may be present. In illustration I report the following case:

Mrs. S., aged thirty-eight years, multigravida, when at the end of the eighth month of pregnancy was suddenly seized with pain and severe hemorrhage from the uterus. I was immediately summoned, for the patient's condition was alarming. The blood flowed from the uterus to the amount of nearly a quart in a few minutes. The finger readily entered the uterus. The os uteri was dilated to the size of a silver dollar and was soft. The uterus was greatly distended. The pulse was very rapid and weak; the expression anxious; the body agitated with tremors and covered with cold sweat; pupils dilated; heart's action weak, irregular and beats intermittent; respiration shallow and hurried; very anæmic.

Treatment was whisky by the mouth and a hypodermic injection of sulphuric ether; the head of the bed was lowered by raising the foot; the vagina was washed out with hot bichloride solution (1:4,000) and tamponed with iodoform gauze. As soon as the patient began to rally the gauze was removed, the membranes ruptured and podalic version performed. The placenta was completely detached. With it there came away several very large clots, about the size of a fœtal head. The child was dead. Mother has made a good recovery.

TRANSLATIONS.

TYPHOID FEVER AND SECONDARY INFECTIOUS ERYTHEMAS.*

DR. L. GAILLARD, PARIS, FRANCE.

GENTLEMEN:

You observed in the Rostan ward a girl of seventeen years affected with a generalized and decidedly desquamative erythema. When you approached her bed she was lying upon her side, her face turned toward the wall, avoiding the light, silent, motionless and prostrate. And when, spoken to by me, she consented to change her position in bed, you noticed a swollen and puffed-up face whose skin was of a uniform redness and about to cast off a number of cuticular scales which were still slightly adherent.

On uncovering her you remarked the scarlet color of the whole surface of the body and the numerous flakes of skin which were easily detached by a touch of the finger-nail. This patient does not have the scarlet fever, for in this disease the desquamation does not coincide with the eruption, there being an interval between the two morbid acts. This case offers a beautiful example of scarlatiniform desquamative erythema. Should we say scarlatiniform? Assuredly, for the scarlet redness is absolutely diffuse, uniform and generalized, and for the moment there is no better term. But remark well, this false scarlatina which I have submitted to your examination only has

*A clinical lecture delivered at the Hopital Saint-Antoine. Translated from La Semaine Medicale, No. 56, 1894, by F. H. Pritchard, M.D.

deserved this term since yesterday. The day before yesterday you would have been quite justified in saying a generalized papular erythema, for then I was able to show you groups of confluent papules with which certain portions of the skin were spared, so that the primordial element of this eruption was not the scarlatinoid patch, but a papule. A day later you might even have called it a polymorphous erythema if there were not discernible here and there slight vesicles, bullæ and other irregularities of this exanthem. I am not one who rejects a precise terminology, especially in speaking of skin diseases, but in this particular instance we may disregard the modalities of the eruption. The prognosis is the special feature here. All the signs point toward a grave state for which the erythema might be called malignant or pernicious. Pathogenically, this eruption is the cutaneous manifestation of an infection, and this infection is secondary to typhoid fever if it be not a variation of the disease itself.

This girl indeed has had the typhoid fever, and it was only when she was becoming convalescent that this formidable complication burst forth. The history of her case is, in short, as follows: Affected with measles at the age of five, she had at two different times suppurating cervical lymphatic glands; at the age of fourteen she first menstruated. January, 1894, she came to Paris to work as a domestic. She had suffered for several days with pains in the ankles, with fever and a disordered stomach. July 23d she felt so weary that she was obliged to lie down before noon; headache, epistaxis, loathing of food, fever and all the symptoms of the beginning of a serious disease appeared. I believe that I am justified in regarding her as being at the seventh day of her typhoid attack when, on July 29th, she was entered brought to the hospital and placed under the care of my colleague, M. Ballet, whom I succeeded on the 1st of August.

When I first saw her on that day a diagnosis of typhoid fever was beyond a doubt: stupor, distention of the abdomen, dryness of the tongue and lips, rose spots, bronchitic râles at the bases of both lungs, with which the clinical picture was complete. The temperature, which until then had remained below 40° C., for the first time went down to 39.1°. August 2d, in spite of repeated sponging, her temperature in the evening reached 40.8°; cold baths were therefore indicated.

It is useless to dwell upon all the details of the evolution of the disease. With cold baths, intestinal antiseptics, especially lactic acid, and then benzo-naphthol, we arrived without incident at the twenty-third day of the disease, when an eschar was noticed on the left elbow, while a vivid redness of both buttocks was also discovered. The temperature still oscillated in the neighborhood of 39°.

The next evening upon coming out of the bath she had a prolonged chill and soon became livid; her feet were icy cold; the temperature by the vagina fell to 34°. We hastened to warm her, injected ether hypodermically, yet the collapse persisted until morning. On the 16th of August, the twenty-fifth day of the disease, her temperature was still very low, 35.6°; she suffered from vomiting of a greenish matter, meteorism, with an exquisite pain in the right iliac fossa, facies abdominalis, cyanosis, but no melæna. These symptoms led us to diagnose an acute peritonitis from perforation and to doubt the existence of intestinal hemorrhage. The prognosis appeared decidedly gloomy. I ordered an ice-bag applied to the abdomen, frappéd champagne and a little opium.

In the evening the temperature had risen to 38.2° and she began to grow warmer. During the days following the abdomen remained distended and painful, but the general condition improved and the temperature varied between 38° and 39.5°. On the 21st, the thirtieth day of the disease, we found an explanation of this persistent fever. Under the eschar of the left elbow a phlegmon had formed. Incision and drainage of the abscess caused the temperature to fall to nearly normal almost immediately. This done, a prompt recovery seemed to be hoped for; but in typhoid fever, as you know, one must always look for the unexpected. Now, on the 31st of August, the fortieth day of the disease, on removing the dressing of the elbow I noticed there a diffuse redness with a tendency to invade the greater portion of the upper extremity. As the day before we had substituted for the usual compresses wet with a solution of boric acid a dilute Van Swieten's solution, it was only natural to attribute the irritation to the sublimate, as I had observed the same condition to follow a salol dressing. I hastened to return to the inoffensive

boric solution, but the impulse had been given, and very rapidly the erythema gained the wrist and the root of the arm, while the papules also appeared upon the other arm, the buttocks, knees, the dorsa of the feet, then the groin, abdomen, neck, chest and face. It was not long before these papules became confluent, and in several portions of the epidermis fine vesicles appeared; on the hands small bullæ and on the soles of the feet large blebs filled with serum. At the same time the tongue began to clear up. To-day, the 9th of September, the erythema deserves to be called scarlatiniform and desquamative. I call your attention to the tumefaction of her face, the prostration, the lack of appetite and the presence of albumen in the urine. I would emphasize the gravity of the symptoms of infection and the malignancy of the disease.

One word upon the evolution of the fever. Since the 31st of August, when the first papules were noticed, the temperature has slowly risen. On the 1st of September in the evening it reached 38.4°; the next day 39.5°; the 3d 40.4°; and finally it reached 40° each evening, becoming somewhat lower in the morning. Yesterday, however, it did not reach 39.4°. The temperature is, in fact, the same as in an ordinary relapse. To recapitulate, we have observed:

1. A fever period of thirty days.
2. A period without fever of six days.
3. A slow ascent of the temperature with oscillations between 38° and 40°.

Internal treatment consists of tonics alone; internally she receives frappéd champagne, which she has drunk since the attack of acute peritonitis, and besides, coffee. Milk is offered her as often as she will take it. Externally a salve of borated vaseline with starch as a dusting powder is employed.

I have abstained from using any of the antiseptic remedies which the condition of infection would seem to demand, as there is not one of them which is not capable of aggravating the eruption and of producing erythemas of themselves.

Here the question is particularly delicate. I have mentioned both salol and sublimate dressings as giving rise to cutaneous irritation. Should we attribute all these symptoms to the dressing alone? Are we to admit a grave mercurial poisoning—a hydrargyria maligna—as we sometimes see in subjects with a peculiar sensibility to mercury? I do not hesitate to state that it is a mere coincidence. That the erythema has begun under and around the dressing is because it has a special predilection for irritated surfaces. Apply, for example, a mustard plaster to the back of a child who is about to break out with the chicken-pox, and you will see the vesicles form especially upon the irritated surface. The same holds true of other eruptions. Besides, I rely upon the evolution of the morbid phenomena in rejecting the hypothesis of a mercurial erythema.

An infectious erythema being admitted, how is it related to the foregoing typhoid fever? Must we regard it as a late symptom, an accident or a complication of the disease? Is Eberth's bacillus or other microbes to be blamed?

Before going into the bacteriology, let us examine the clinical side. You know, firstly, that this exanthem is by no means an ordinary symptom in the disease; it is indeed exceptional. Among the physicians whom you might consult on this subject several would confess their ignorance; others will say that they have observed it two or three times during a long practice; still others will state that they have long looked for but have never met with it. And if you open your books you will find but a meager number of observations.

The earliest is that of Forget (1843), which was of a scarlatiniform erythema appearing on the tenth day of the fever; then follow the cases of Mazeron (1866), Eichhorst (1875), Normand (1875), Murchison, Cottle, Reymond and Nélaton (1878). In 1880 Maurice Reynaud began to infuse a little order into the description of the eruptions of typhoid fever which he divided into early and late manifestations. Since this epoch there are works of Keromnès, Reynaud, Lemaigre, Lory, Moore, Hutinel and Martin de Gimard, Mussy, Legendre.

A perusal of this literature permits one to assert that besides the usual rose spots there are in this disease several varieties of erythema which may be considered from three points of view: the epoch of appearance, clinical physiognomy and gravity.

I. *Epoch of Appearance.*—Certain erythemas may precede the rose spots. They are called early and even premonitory, for

they have been called "rashes." In two of Wepham's cases they were scarlatiniform. Others are noticed after the first week and the rose spots in the second and third weeks. Still others are observed during convalescence, either with disappearance of the fever or after a few days of normal temperature. In relating the history of our case I have shown that the erythema constituted a sort of relapse, in which the process exhausted itself in the skin instead of Peyer's patches. Hence we may designate it a pseudo-reversive erythema. Though with the eruption it is evident enough, I should not dare to affirm the integrity of the patches, for in a case reported by Legendre last year before the Paris Hospital Society the erythema was connected with an actual relapse. It appeared on the sixty-first day of the disease, the relapse setting in on the forty-second, and the necropsy demonstrated the truth of the relapse. On the hundred and second day there were still ulcerations in the intestines.

Clinical Physiognomy.—Some authors have observed the scarlatiniform or morbilliform rash, but this is an exception. In the majority of cases the eruption is characteristic and observed in all infectious diseases. Whenever it may appear it is first noticed upon the backs of the hands, wrists, elbows, legs, knees and buttocks as rounded macules or papules but little elevated above the skin and disappearing under pressure. At first isolated, they soon confluesce and form patches which are symmetric. This is the beginning. In certain cases the eruption extends until it involves the entire body in a uniform and scarlatiniform rash. But this is not all. The papules may become covered with vesicles, bullæ or pustules. On an average the eruption does not last more than five or six days, and it is before the disappearance of the red tint that desquamation sets in. When the patients survive this, follows slowly in large flakes, as in scarlatina. It corresponds more or less with the intensity of the eruption.

Gravity.—Several writers have regarded these rashes as devoid of importance. Raymond and Nélaton declare that its influence was only favorable in their three cases and without characteristic impression on the disease itself. Chédevergne also saw a salutary influence from the cutaneous congestion. We to-day must look at this more pessimistically, for in typhoid-fever subjects infectious erythemata have claimed enough victims to force us to regard them as malignant and carrying a gloomy prognosis from the moment that the first papules are seen. Out of 12 cases of Hutinel and Martin de Gimard there were 7 recoveries and 5 deaths; in those of Legendre 3 deaths. And among those that recovered several had a terrible struggle for life.

Therefore, in my opinion, we must hold by Nélaton's and Raymond's statement that every erythema appearing either at the stage of full development or in convalescence is an indication of a severe infection.

What is the exact nature of this infection? Streptococci play an important part in certain typhoid subjects. The bacterium coli has also been incriminated. Very recently Bosc described it as of an intestinal infection from a microbe resembling the bacterium coli. Numerous microörganisms might easily enter the organism through various points of entrance, as the ulcerations of the intestines, the excoriations of the skin and mucous surfaces. Hutinel emphasizes the importance of labial fissures, aphthous erosions of the lips and mouth, erosions of the nose and ulcerations of the throat which he observed in his patients. In our case the eschar on the elbow and the succeeding phlegmon formed important foci of microbic activity Whatever it be, beware of looking slightingly on cutaneous efflorescences. Use no internal antiseptics which may aggravate the exanthem, and only give tonics. Give alcohol but moderately, as albuminuria is the rule in grave cases. Prescribe alkaline drinks and milk. If the temperature rise do not fear to advise cold baths. Calm the cutaneous irritability by emmolient salves and inert powders. Be on the watch for visceral complications—endocarditis, pleurisy or broncho-pneumonia. Examine the abdomen frequently, for the erythema may be the sign of a return of intestinal changes.

Is there a danger of contagion and should the patient be isolated? Certainly, though the risk is slight. Whenever the cases appeared in a series the list has been noticeably short. The 3 cases of Raymond and Nélaton concerned three persons in the same ward. That was in 1878,

when this disease affected Parisians with greater severity than at present. Legendre also reported last year 3 cases in one ward in typhoid-fever patients and 1 in a case of Bright's disease. But the only epidemic worthy of the name is that described by Hutinel and Martin de Gimard. It occurred in 1889 at the Children's Hospital. From June 1st to December 1st there were 38 cases of typhoid fever, and of these 12 were affected with infectious erythema, and that from the beginning of September and in two distinct wards. *But only the typhoid cases were affected* and none of the more or less debilitated children who lay in the neighboring beds. Thus this pretended epidemic attacked only the typhoid subjects and respected the others. You can understand my skepticism.

Besides, if you desire further information look outside of the narrow limits of this disease, for these erythemata are not the exclusive property of typhoid fever. They are observed in diphtheria, septicemia, in puerperal infection, gonorrhœa, and especially in cholera. In this latter disease it is much less rare than in typhoid fever. I have observed it in 1892 in 21 cases out of 400. Some authors hold it to be still more frequent. Duflocq has reported 18 cases in 215. Now, this eruption has a singular similarity to that of typhoid fever. The papules begin on the backs of the wrists, on the forearms, the ankles, around the knees, the buttocks and are symmetric. They then invade other regions, forming large plaques which may become scarlatiniform and desquamative. In my experience with the cholera I have not observed a single fact which might explain the contagiousness of the exanthem. Among the many physicians who have cared for these patients, none has believed in the transmission of the eruption by artificial means. More work is necessary to fix the bacteriology of this erythema after typhoid fever.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

PNEUMONIA IN CHILDREN.

Dr. D. C. Loewenthal (*La Semaine Médicale*, No. 66, 1894) recommends as an efficient measure to control the high temperature of pneumonia in children the following formula:

Phenacetine.....	āā o	06	gr. j
Sulphate quinine.....			
Caffeine.....	āā o	01	gr. 1-6
Benzoate soda.....			

For one powder. Make twelve such. One every two to four hours in a child of sixteen months.

BONE-MARROW IN ANEMIA.

Drs. Fraser and Begger (*Wiener Medizinische Presse*, No. 44, 1894) have obtained very satisfactory results with marrow of bone in the treatment of anemia. The former had under his care a man who had suffered for several years with grave anemia where the different preparations of iron and arsenic were inactive. The patient was ordered to eat daily one hundred grams (over three ounces) of the marrow of beef and calves' bones; iron and salol were also given at the same time. In three weeks there was a distinct improvement of his general condition, which was apparent in an increase of the hemoglobin and the number of blood corpuscles. Several weeks after this the patient was able to go to work. Dr. Begger employed this treatment in a boy of twelve years who had suffered for a long time from splenic leucemia, which in spite of iron and arsenic in large doses continued to become worse. At the time of beginning treatment he was very weak; his spleen filled nearly the whole left portion of the abdomen, reaching to the iliac fossa on that side and extending five centimeters over the median line. There were besides, fever, diarrhœa, frequent nose-bleed, dyspnœa and palpitation of the heart. Three or four times a day he received a piece of bread to eat upon which was spread a thick layer of raw marrow. In eight days the icteric color of his skin had disappeared; the fever ceased, the dyspnœa and palpitation vanished in two weeks, while the spleen decreased somewhat in size. The organ gradually diminished in size and the child recovered fully.

BICARBONATE OF SODA IN ARTHRITISM.

Dr. A. Cavazanni (*La Semaine Médicale*, No. 66, 1894) has found the bicar-

*In chage of the translator, F. H. Pritchard, M.D.

bonate of soda to be the best remedy in the treatment of the articular and muscular pains, either with or without swelling, of arthritic patients. It must be given for a long time, in doses of one to four grams (grs. xv–3j) a day. With this simple and efficacious measure he has succeeded in relieving eight cases where other remedies had failed. He would not advise its administration in powder, but rather in a weak solution while the stomach is empty.

LARYNGEAL STENOSIS OF DIPHTHERIA.

Dr. Brenner (*Muenchener Medicinische Wochenschrift*, No. 44, 1894) in two cases of laryngeal stenosis from diphtheria observed a remarkable relief by application of cantharidated collodion to the region of the thyroid cartilage to the extent of a spot of the size of a dollar.

CHLOROFORM IN LABOR.

Dr. M. Latta (*La Semaine Médicale*, No. 66, 1894) administers chloroform to all his cases of labor, even if they are perfectly normal in course. In those cases presenting a weakness of the heart he employs a mixture of chloroform and amyl nitrite, containing ninety parts of the former to one of the latter.

UTERINE COUGH AND ITS TREATMENT.

Dr. P. Profanter (*Revue Internationale de Medecin et de Chirurgie Pratiques*, No. 18, 1894) has observed a goodly number of those cases which were described by Aran as uterine cough and which is a reflex affection accompanying various chronic diseases of the female genital organs. The cough being very persistent and occurring in emaciated and weakened women with chronic gynecological diseases, one might easily be misled into making a mistaken diagnosis of pulmonary consumption. The cough is dry, hacking and sometimes hoarse, setting in after the uterine disease has become chronic. Its aggravation during the menstrual periods may set one upon the right road to diagnosis. Bimanual examination will reveal particularly painful points in the pelvis which, upon pressure, will provoke an attack of coughing. Treatment should be directed toward the original affection, yet only at once in robust patients, for in nervous, weakened and irritable women local treatment may cause a distinct aggravation. Therefore the general health must first be improved by hygiene, hearty food, forced feeding, treatment of the concomitant gastro-intestinal symptoms as well as by a quieting the general over excitability by the bromides, hydro-therapeutic measures, etc., while local measures are reserved for a later period. Locally one may employ vaginal injections of hot saline solution and warm compresses to the abdomen.

THE DIFFERENT VARIETIES OF DIET IN CHRONIC BRIGHT'S DISEASE.

Dr. W. H. White (*Hospitals-Tidende*, No. 44, 1894) is at variance with the accepted ideas of the ideal diet in chronic Bright's disease. He has made a series of experiments with regard to the solution of this question. Milk diet is generally advised, as it is thought to cause a decrease in the quantity of albumen excreted by the kidneys. He has found this far from true in his cases. As a rule, the albuminuria remains unaffected by any variety of diet, even with consumption of a large quantity of albumen. In those cases with a great amount of albumen in the urine this fact of itself is not of such importance as is generally considered. He has seen cases where the loss in albumen was less with a mixed diet than with one of milk and carbohydrates. The albuminuria is not the most important symptom and a treatment directed against this alone is faulty. Milk is said to be both easily digestible and diuretic. The former is not always the case, and as to the latter it is doubtful if diuretics will do good in this disease. Milk is also thought to favor elimination of the toxic substances, which is again doubtful. He has found a mixed diet to give the best results in practice. It did not produce uremia, the general condition and strength of the patient remained better and the circulation was stronger than with milk and carbohydrates. It strengthens the system against the loss of the albumen, as the ingested albumen covers this loss. Mixed diet is also better tolerated, gives rise to no disgust nor anorexia as the milk and carbohydrates sometimes do.

CHRONIC SCROFULOUS OTORRHŒA.

Dr. Isaia (*La Semaine Medicale*, No. 64, 1894) has obtained good results in the

chronic otorrhœa of scrofulous subjects with either of the following formulæ:

Balsam Peru.....	ää 10	o	ʒijss
Alcohol.....			
Muriate cocaine....	0.50–1	o	grs. vijss–xv
Balsam Peru.....	5	o	ʒij¼
Glycerine.....	10	o	ʒijss
Muriate cocaine....	0.5–1	o	grs. vijss–xv
Balsam Peru.....	ää 2	o	grs. xxx
Balsam tolu.....			
Alcohol.....	5.0–10	o	ʒij¼–ʒijss
Muriate cocaine....	1.0–2	o	grs. xv–xxx

Having previously cleansed the ear either with a solution of resorcine, boric acid or simple salt and water, the walls of the canal are anesthetized by a few drops of a solution of cocaine, after which a little of one of these solutions is instilled into the ear or it may be applied on a pledget of cotton. In nearly every case this treatment will give good results, but it is only indicated when the skin of the external ear and auditory canal are intact, for if it be excoriated the irritating qualities of the balsam might lead to painful inflammatory complications.

ALOPECIA AFTER ACUTE DISEASES.

Professor Kaposi (*Revista de Ciencias Medicas de Barcelona*, No. 16, 1894) in the treatment of falling out of the hair during convalescence of acute diseases, cachectic states, and women after confinement, recommends highly the following formula:

Alcohol.....	200	o	ʒvjss
Veratrine.....	o	50	grs. vijss
Tinct. benzoin	1	o	gtts. xv
Salicylic acid	o	50	grs. vjss

Apply locally.

Dr. Brocq (*ibid.*) advises the following in same condition:

Tinct. lemon peel.....	150	o	ʒiv¾
Hydrochloric acid.....	4	o	ʒj

Apply locally.

ELECTROLYSIS IN RODENT ULCER.

Dr. I. Parsons (*Norsk Magazin for Lægevidenskaben*, No. 11, 1894) has obtained very good results in rodent ulcer with electrolysis. It is not accompanied by hemorrhage and its action may be limited to the affected part, while the operation, which is done under anesthesia, is followed by no pain. Two needles are employed with a current of two to four hundred milliamperes with continuous alternation of the current. The resultant eschar will fall off in eight to ten days, the wound heals readily and a firm cicatrix results. In case of recurrence, repeat the operation.

TREATMENT OF EPITHELIOMA OF THE SKIN.

Dr. Darier (*Norsk Magazin for Lægevidenskaben*, No. 11, 1894) has treated with success five cases of cutaneous epithelioma in the following manner:

The crusts are removed by antiseptic poultices of potato starch boiled in a 1:1,000 solution of the bichloride and the ulcer is anesthetized with a ten per cent. solution of cocaine; then it is painted with the following:

Methyl-blue.....	1	o	grs xv
Alcohol.....	ää 5	o	ʒij¼
Glycerine.....			

All the blue-colored spots are then touched with a twenty per cent. solution of chromic acid, which changes the color to purplish-red; a second application of the methyl solution is again made. The ulcer is then covered with a sublimated dressing. This treatment is repeated four to five times, with intervals of two or three days, but the methyl-blue is only to be used as long as the new-formed skin takes up the coloring matter. This method is not painful and is very rapid in its results. In superficial epitheliomas from three weeks to two months are sufficient for a cure—about one month to the square centimeter. In deeper infiltrations one may also employ injections of the methyl-blue together with the local applications, but here chromic acid must be applied with great caution.

TREATMENT OF BURNS OF THE EYES BY AMMONIACAL VAPORS.

Dr. Trousseau (*La France Médicale*, No. 47, 1894) recently read a paper before the Medical Society of Paris on the effects of vapors of ammonia upon the eyes and their treatment. He divides the lesions into three degrees. These states are those caused by the vapors and not the entrance of the liquid into the eye. The effects of the first degree, hyperemia, photophobia and lachrymation, may persist for several days, and if somewhat advanced there may be swelling of the conjunctivæ, purulent secretion of more or less abundance which causes the lids to adhere; the cornea will be found intact. Compresses wet in tepid boric-acid solution and frequently renewed will bring about a restitution in a few days.

In the lesions of the second degree the condition is the same, with the formation

of eschars upon the conjunctivæ which render symblepharon prone to follow. This is best avoided as much as possible by frequent movements of the lids and the introduction, now and then, of a little vaseline between the lids. In the burns of the third degree the symptoms of irritation are much more pronounced. Even five or six days after the accident the conjunctivæ are reddened, violet-colored, œdematous and secrete muco-pus. Though the corneæ are apparently intact, one should not make too favorable a prognosis on account of the liability to symblepharon and the formation of corneal opacities. A deceptive amelioration may set in after a short time, to be followed by the appearance of milky white and complete opacity of the cornea. The eye may be seemingly intact for some time, while really it is severely affected. He warns against the danger of incautiously opening bottles of ammonia or of letting the vapors come into contact with the eyes.

TREATMENT OF LEUCEMIA.

Dr. Vehsemeyer (*Rivista Clinica e Terapeutica*, No. 10, 1894) thinks that all the remedies proposed in the treatment of leucemia are not only inactive but incapable of modifying, in the slightest manner, the course of the affection. He has found berberis vulgaris, either in fluid extract, pill or powder, to be a most excellent remedy in this disease. He calls attention to its elective action upon the intestine and the appetite. In one of his numerous cases where he tried this drug the results were truly marvelous. The patient, a young lady of a weakened appearance and of a delicate constitution who was affected with leucemia to an extreme degree, under the influence of this drug soon felt decidedly better, her appetite and intestinal functions greatly improved and the spleen decreased very much in size. This result was obtained without any particular attention being given to the diet, which, however, he thinks an important accessory. He advises an increase in carbohydrates in the dietary.

THE BISMUTH TREATMENT OF GASTRIC ULCER.

Dr. Savelieff (*Muenchener Medicinische Wochenschrift*, No. 45, 1894) reports from Professor Senator's clinic in Berlin that the treatment of gastric ulcer with the subnitrate of bismuth has given there excellent results. Ten grams (ʒijss) of the drug are taken at one time suspended in two hundred grams (℥vj ʒij) of water, and that portion of the subnitrate remaining in the upper portion of the œsophagus and mouth is washed down with a few swallows of water. If washing out the stomach is necessary, then this mixture is introduced through the stomach tube. A cure is generally obtained with the ingestion of two hundred grams of the drug. Immediately after taking it the patient is instructed to lie down for about an hour. In this position the ulcer is easily covered with the fluid, and still better if the hips be elevated about fifteen centimeters. Naturally the ordinary dietetic restrictions are to be followed. Nearly all the patients attended to their business during the treatment.

TREATMENT OF RECURRENT ECZEMA OF THE UPPER LIP.

Drs. Perrin and Aslanian (*La Semaine Medicale*, No. 64, 1894) in the management of recurrent eczema of the upper lip recommend cutting the mustache short and applying locally, several times a day, a supersaturated solution of boric acid in absolute alcohol. This will destroy the staphylococci aurei which they claim are normally present on the upper lip and around the nostrils, either alone or associated with other microbes, and which play so important a part in the production of eczema of the hairy portions of the body. Care should be taken not to take cold, as the consequent purulent discharge will aggravate the disease.

CORRESPONDENCE.

THE BOARD OF CHARITIES AND CORRECTION—OF MEDICINE.

EDITOR MEDICAL AND SURGICAL REPORTER—SIR:

The profession of Philadelphia by the action of the Board of Charities and Correction dismissing a conscientious, progressive and scientific physician from the staff of the Philadelphia Hospital, has received a shock which has shaken it throughout its entirety, which threatens the integrity of the conditions upon which its growth and development depend, and which calls for explanation and protest and for an effort to secure protection from a repetition of such a serious onslaught and from the chagrin and shame which must be suffered until the citizens of the Commonwealth understand and appreciate the principle threatened and the injustice and wrong perpetrated.

Tersely the procedure may be stated to be that for instituting means of determining an accurate diagnosis and employing instruments of precision essential thereto, a board, composed of four laymen and one physician, ignominiously discharged a physician from the staff and publicly censured and falsely charged him with criminally experimenting, permitting patients to suffer untreated in order to subserve some ulterior motive.

It is needless to unbury the history of the world's persecution of those who established truth and demonstrated principles underlying progress and development in every sphere of life, whether in religion or the sciences, but to direct attention to the fact that the same power of ignorance to-day occupies positions where the relationships are improper, and that the vital forces and principles upon which the advance and the conditions determining a nearer approach to the perfection of the art and science are in danger of serious injury. Inability to comprehend the discoveries of value with which vivisection supplies the profession explains the existence of that well-meaning but densely obtuse organization of sentimentalists known as the Anti-Vivisection Society; parallel ignorance is the soil from which anti-vaccinationists have sprung; small mentality gives us the mushroom growth of the "pathies" and the unfortunately ignorant or naturally stupid brethren who either can't or won't advance, and will, by reason of their deficiencies, cry out in opposition to progress and betterment, are the pitiable monuments to retrogression. To such, both lay and professional, it is time that processes of education and control be directed.

Misrepresentation is the invariable method of their obstructionist attacks, and indeed it cannot be otherwise, for to state a conclusion which is a misunderstood or uncomprehended truth is to falsify. A lie is modified truth. It is not intentional when the result of well-meaning ignorance, and this it is which renders it venomous, especially when emanating from one who in matters within the sphere of comprehension is recognized as honorable and truthful. Illustrations of the unintentional misrepresentations are had in the English Government, where honorable representatives, by proclaiming their convictions (misunderstandings), created such a sentiment that a law was enacted prohibiting vivisection, and thus was delivered a blow at the principles of progress which was of sufficient power to stop the wheels of knowledge in that direction for years. The investigation of the poison of venomous reptiles from which annually many thousands of English subjects die, having for its end the discovery of medicines that would avert the fatal consequences of snake-bite, was—think of it!—prohibited by law, and thus for years while a few animals were saved thousands of human lives were sacrificed. To the bulwark of American scientific medicine, the University of Pennsylvania, intelligent England turned for deliverance, and forwarded to us reptiles so that the investigations could be continued. The results more than justified and demonstrated the value of the application of the principle of progress and truth. Sunstroke, our summer destroyer, was not understood until Professor Wood a very few years since investigated its effects and discovered how

its fatal results were occasioned, and notwithstanding that annually lives are saved by the hundreds as the result of this scientific labor, the same evil spirit of misrepresentation periodically attempts to enact laws preventing similar scientific studies.

Does the profession prove true to its principles when it quietly submits to wounds inflicted upon any portion of its functional life without resentment? Is it to be subjected to dethronement by the authoritative power of ignorance because it does its duty properly and well? Are we to be persecuted because we employ means to determine correct diagnoses and establish proper methods of treatment? Are we to be subjected to mass opposition and misrepresentation on the part of the ignorant and rendered liable to damage suits because processes of advancement and betterment and a higher science are being practiced? Let us see to it that with the intelligent our cause is made known, and either deprive lay committees and boards of directors having supervision over medical institutions of their jurisdiction, or secure the establishment of such bodies composed of enlightened medical gentlemen who can understand the principles underlying the betterment and progress of the profession and who will earnestly advocate and secure upon a firm foundation the best conditions for the best ends.

The medico-legal bearing of the act of the Board of Charities and Correction recently chronicled is particularly striking. Suppose a peculiarity of a fracture could best be treated by the application of a modified dressing which would secure a more nearly perfect result than that which would follow the employment of an orthodox splint, and a slight degree of deformity still exist and the patient should institute a suit for damages. In the evidence would appear the fact that the orthodox dressing was substituted by a more desirable modification, and what would then be the position of the surgeon? If the jury were composed of such minds as characterizes the Board of Charities and Correction, it would be better to engage in some other vocation in life. Is the comparison not true? Unless Dr. Daland "feeds" quinine at once to a malarial case without first ascertaining the exact condition of the sufferer and definitely determining the degree of damage to the corpuscles and hæmoglobin, he is to be publicly censured and persecuted.

This, then, is the fact: no member of the staff of the Philadelphia Hospital dares to perform his duty as a scientific physician under the regulations of the Board of Charities and Correction as at present constituted without incurring the risk of public censure and dismissal. To the citizen who is taxed for the support of his unfortunate fellow-being and for the best interests of the afflicted the physician owes and—it may be said with pride—gives his best talents; and when the exercise of this is regulated or controlled by such conditions which, to the discredit and shame of this medical center, are permitted to exist at the Philadelphia Hospital, it is time to effect a change.

Truly, the board did not intend to act so reprehensibly and disgracefully; it simply did not know better, and they should therefore not be censured, but replaced by one that possesses the requisite intelligence necessary to enable it to comprehend, appreciate and aid the scientific and enlightened physician in the faithful discharge of his duty to the best interest of the institution and the best good of his patients. This can best be effected by the establishment of a medical board composed of medical gentlemen only and a business board composed of business men, each having jurisdiction only over its particular territory; and it is the duty of every member of the profession to do all in his power to accomplish this end.

Very truly,

H. Beates, M.D.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, DECEMBER 22, 1894.

EDITORIAL.

THE DETERMINATION OF SCIENTIFIC MEDICINE BY POLITICS.

The action of the Board of Charities and Correction in removing Dr. Judson Daland from the professional staff of the Philadelphia Hospital contained a genuine surprise for medical practitioners, if not for medical professors and politicians. It was not the gross injustice done an individual, nor the rebuke to conscientious performance of duty, nor yet the outrage to inoffensive efforts to advance humanitarian science, that distinguished the surprise. These items might provoke comment, but could scarcely cause amazement, for, unfortunately, they are of too frequent occurrence. It is a matter of common observation that individual qualifications and trained excellence carry no weight as compared with "influence" in formulating the decisions of bodies of professional philanthropists who are administering public trusts. The surprise in this instance is that the fiction is stranger than the fact. The reason assigned by the board for their unjustifiable action is a marvelous exhibition of novelty, simplicity and *naïvete*. It is novel, in that it is the first medical bull publicly made by the new faculty of municipal science; its simplicity is so unmarred by intellectual adornment that it reaches but a step from the sublime. Its *naïvete*, or knavery, is as patent as its simplicity. But this official dictum will relieve the public of speculating as to the significance of some matters which, presumably are merely coincidences. The members of the board have assigned a reason, and this must be accepted, for they are all honorable men.

If any should consider this reason too attenuated to stand unsupported, in justice to the Board of Charities and Correction they should bear in mind the fact that this is the first public appearance of that organization in the *rôle* of an authority in medical science, and furthermore that every-day familiarity with the wants of the needy and with the iniquities of the vicious enable them to take cognizance of influences which do not appear on the surface, and the revelation of which might prove detrimental to the public welfare. Similar instances are not unknown in other diplomatic circles. It violates no confidence to say the explanation offered is,

within our knowledge, the only ostensible reason.

From creditable information at hand the matter stands about as follows:

Dr. Daland is one of the hardest workers in the medical profession, most of his time being spent in original research. He has just finished his second year at the Philadelphia Hospital as a visiting physician. Since his election to the staff he has spent most of his time in the wards, frequently serving for other physicians in emergencies.

The terms of all the medical staff expire with the year. Usually they are all reëlected. When the board met recently the election was about the last thing done, and not a word was said about any change of any kind. Each member prepared his ballot and handed it in, and the result showed the reëlection of all the staff excepting Dr. Daland.

The board assigned as the reason for not reëlecting Dr. Daland that it objected to a certain kind of treatment which he used. It is alleged that while treating some patients who had malaria he did not give them quinine at a certain stage in the disease because he wished to take a few drops of the blood during the chill accompanying the complaint so that he might examine it with a view to advancing medical science.

The president of the board, asked why this action was taken, finally said: "Because the board preferred the other man. The board differed with Dr. Daland in a matter of treatment of patients; that is all. Personally I have the greatest regard for Dr. Daland. I admire him for his abilities and for the work he has done. But with other members of the board, I disagreed with him about certain matters of treatment, so I voted for the other man." Incidentally no complaint had been made by patients subjected to this inhuman barbarity.

Dr. James W. Walk, who was the only member to support Dr. Daland, is quoted as saying: "My position is this: The question of medical treatment in the hospital is a technical matter, and I do not think that laymen are competent to decide it. If the board has any objection to any method of treating patients, it ought to have a commission of physicians pass upon it. It doesn't seem to me to be in the sphere of the board. Dr. Daland has labored so faithfully and so well since he has been at the hospital that I did not think we ought to drop him because of treatment, the merit or demerit of which is a medical question."

Dr. Horatio C. Wood, who is accustomed to use plain terms when he unburdens his mind, in a public interview said, among other things:

"As a result of careful inquiry it was evident that the allegations made by the Board of Charities were not only untrue, but that at the time of the voting in the afternoon, if these gentlemen did not know that these allegations were untrue it was because they had failed to investigate. The patients were treated, though not with quinine. So that the Board of Charities has arrogated to itself the right to decide not only that no experiments shall be made in the hospital, but that a physician shall be removed because his treatment does not meet the approval of the Board of Charities.

"Allowing, however, for the moment, that in this arrogation of the Board of Charities it is acting wisely, it is plain that in removing Dr. Daland they acted unjustly in that they failed to notify the medical staff that they did not consider any of its members had the right to make any experimental studies in the hospital.

"The greatest danger that threatens the medical prestige of Philadelphia is, in the first place, because the medical laboratories are not supported by the people of the city; and in the second place, because

the Philadelphia City Hospital is administered in such a way as to make it almost impossible to use it for the increase of medical knowledge. It is not because there is lack of ability in Philadelphia or lack of men willing to make the personal sacrifice that we have to go abroad for our medical discoveries, but because the mayor habitually puts in charge of the Philadelphia Hospital and gives so much power in the hospital to them, men, honest that may be, but without natural force of intellect which will allow them to take broad views of important problems. It is perfectly true that no physician has the right, for the sake of furthering human knowledge, to endanger human life. But medicine is an experimental science, and can only grow by experiments and the experiment which is based upon rational groundwork and is carried out with care, does not endanger human life or human body integrity, is not only justifiable, but imperative. It was for spending his time, without hope of any direct personal reward, in such labor and in such a way that must lead to results, that the Board of Charities and Correction removed Dr. Daland, and in such a removal struck a great blow at the medical interests of the city and of the world."

Possibly the Board of Charities and Correction was panic-stricken at the thought of a visit from avenging zoöphilists with their formidable lachrymal engines run by sentimental accumulator cells. Certainly some powerful agency disturbed its equilibrium.

While THE REPORTER agrees with Professor Wood in his estimate of the effect upon medical Philadelphia resulting from the narrow policy obtaining in the management of municipal charities, it believes that there is another and even greater danger to medical prestige for which the profession itself is responsible and which permits of the existence of the conditions complained of. So long as medical opinion sanctions or even tolerates the existence of that form of multilocular (*multus*, many; *locus*, position) parasitism which monopolizes public appointments to the detriment of science and institutions alike, there can be little hope for satisfactory progress in scientific medical research.

While civil and medical politicians are playing into each other's hands, the pot must not call the kettle black.

ABSTRACTS.

THE INJUSTICE OF COMPETITIVE CHARITY.

Has the medical staff nothing to say as to unlimited endowing of free beds in enterprising hospitals, and the free treatment of anybody and everybody, upon payment of nothing or of some hypocritically small fee? Is this simply and solely a matter within the control of lay boards of trustees and of professional philanthropists? These questions are suggested by a widely distributed circular issued by a large hospital in a city of the eastern United States which reads as follows:

> The Board of Trustees of the —— Hospital of the city of —— strongly recommend the following advantages offered to the public.
>
> Mill and factory owners, lodges, and beneficial associations can secure a bed at the —— Hospital for 365 days by paying $200, and upon averaging the days may have several patients in the hospital at the same time.
>
> Subscription books can be obtained by working people of both sexes up to the

age of fifty, subject to the regulations of the hospital, whereby, on paying an initiation fee of one dollar and monthly installments of fifty cents, each subscriber may be treated in case of sickness entirely free of further charge. Heads of families and owners of factories should particularly recommend to their servants and employees to avail themselves of this excellent facility.

Of course, if the medical officers of this hospital have assented to this plan, nothing more in criticism can be said except to ask them:

1. Have you any right to assent to it for *other* physicians who in the course of human events may take your places by and by?

2. If all hospital staffs assent to it, have the non-hospital physicians no criticism to offer and no rights to be upheld?

3. Has the medical profession nothing to suggest as to the encouragement of pauperism and the just claim of members of the profession to some compensation for medical services from those able to pay? Has the public no duties to the medical profession in this debauching competition in "offering advantages to the public?"

4. By what principle of common justice and decency can it be claimed that well-to-do "workmen, lodges and beneficial associations" are unable to pay medical men something for their services, and that the professionally benevolent should dispose of medical service by virtue of being trustees of hospitals?

In England the impudence of these trustees and dictators of medical men has become a public calamity, and the same trend is more than evident here. Have medical societies and associations, colleges and academies of physicians, no word to utter as to the huge and growing abuse? Instead of permitting or encouraging, they should warm the endowers, supporters and trustees of hospitals and the easily deceived public that the blind sentimentalism of charity almost inevitably ends in wrong and ruin, and that whatever injures the medical profession in the long run injures the health and well-being of the general pubiic.

Not a dollar should be given to any hospital that is not accompanied by an express stipulation on the part of the giver, and by a promise as explicit on the part of trustees and officers, that no person (except in emergency cases, etc.) shall receive medical aid in the institution except it have been systematically and clearly made evident that such person is unable to pay anything for the service. Medical men are already overburdened with necessary or inevitable charity work in private, hospital and dispensary practice, but they display a criminal negligence as regards the increase of this evil of charity abuse, and either supinely submit to the dictatorship of mechanic routine or of trustees, and even go so far as enthusiasm in professional hari-kari. It is high time the brakes were applied.—*Med. News.*

THE "OYSTER EPIDEMIC" OF TYPHOID FEVER AT WESLEYAN UNIVERSITY.

H. W. Conn, Ph.D., professor of biology, Wesleyan University, Middletown, Conn., writes (*Med. Rec.*): While it has been for some time suspected that raw oysters may be a possible means of the distribution of germ diseases, there have been no cases where the theory has been positively demonstrated. The recent outbreak of typhoid at Wesleyan University is, in this respect, therefore, so unique as to be of especial interest, and for this reason the results of the investigation as to the cause of this outbreak are given below in some detail.

The history of the epidemic was as follows: About October 20th there began to appear among the students a number of cases of mild fever, which were for several days not regarded as serious. After about a week, however, one or two of them developed into typical typhoid fever, and several others were suspected of being of the same nature. For a week and a half following October 20th new cases appeared somewhat rapidly, and by November 1st there had appeared among the members of the college about 23 cases of fever of more or less prominent typhoid character. After November 1st the number of cases diminished, although 2 appeared on November 2d, 1 on November 5th, and 1 as late as November 9th. Subsequent to

that period on new cases have developed. There have been among the students about 26 cases of fever which have been, with more or less reason, regarded as typhoid. Of these 23 have been pronounced typhoid by the physicians in charge, while the others are of such a slight nature and have so few typhoid symptoms as to make it at least doubtful whether they were really typhoid fever. Of the cases of undoubted typhoid, 13 have been very serious and the others not very serious. Four deaths have occurred, and at the time of writing there are one or two other patients in a critical condition. It will be noticed from these facts that the outbreak of typhoid fever in college began about October 20th and the last case appeared about November 9th.

As soon as the serious nature of the disease was recognized an investigation as to its cause was begun. Of course, at that time it was not known that the disease would be limited to the dates above mentioned, and it was regarded as possible that there was in college a constant source of infection. The students that were sick were found to room in all of the college buildings and also in several houses in town. Moreover, it was seen that they did not board at the same boarding-place, and there appeared at first, therefore, to be no connection between them except the college campus. The first object of suspicion was the water from two wells at the back of the college buildings, which was used occasionally by the students of the college for drinking purposes. On this suspicion the use of the water was immediately stopped, and an examination of the wells was made. Chemical examination showed in one of the wells an exceptionally large amount of albuminoid ammonia. The examination was made immediately after a heavy rain following a long drought, which might possibly have accounted for this. A bacteriological examination was set on foot according to the method of Professor Vaughn. Bouillon cultures from the water of each well were made and cultivated for two days in a culture oven. Then 20 c.c. of the culture was inoculated into the abdominal cavity of white rats. The white rats, however, were entirely unaffected by the treatment, indicating plainly that pathogenic germs of a typhoid nature could not have been present. Moreover, a little inquiry showed that the wells could not have been the cause of the trouble. In the first place several of the students who were sick had certainly not drank from either of the wells. Secondly, the wells were used almost as much by certain young people from the town as by the students themselves, and there was no corresponding outbreak of typhoid in the city. In fact, Middletown, at the time, proved exceptionally free from all kinds of fevers. These facts taken together made it necessary to exclude the wells from the possible sources of infection.

It was noticed at the outset that the ladies of the college, about fifty in number, were exempted from the disease. This, of course, indicated that the cause of the infection could not have been in any unsanitary condition connected with the public college buildings in general, but must have been some source of infection to which the young men were exposed, and not the young ladies. After carefully looking over the facts it was further found that all of the cases of sickness, with three exceptions, occurred in three of the college fraternities. The men did not all room in the fraternity buildings, though most of them did board at the fraternity club houses. This localizing of the disease to three fraternities proved the first usable point of departure in the investigation.

In the college there are seven fraternities, and most of the college students board at the fraternity clubs. In the three fraternities afflicted there were about 100 students, and among the 100 students, as above stated, about 25 cases of typhoid developed. This is seen at once to be an extremely large proportion. It is usually supposed that some 10 to 15 per cent. of those exposed to typhoid take the disease, and here was a percentage at least twice that proportion. This large percentage indicated at once that there must have been some extremely virulent source of infection to which probably every member of the fraternities was subjected. In no other way could the large percentage of cases among the students be accounted for.

In the attempt to locate the source of the trouble in connection with the three fraternities, however, every source of possible contagion was investigated. The plumbing was examined, and though

found to be defective in at least one case, in the other houses it was in first-class condition. It was hardly possible to accuse the plumbing, however, inasmuch as the three clubs afflicted were situated at a distance of half a mile from each other and were connected with different sewers. The probability that these three houses should have been defective in their plumbing at the same time was very remote, and their connection with different sewers, together with the absence of typhoid in the city, made it impossible to accuse the plumbing. The possibility of transference of the disease from house to house was also considered, an attempt being made to find some early case which could possibly have been a source of infection to the other houses. But this proved futile. There were no early cases, for almost at once, upon October 20th, two or three cases developed simultaneously, and of course this made it impossible to explain the epidemic by personal contagion. It was found, moreover, that the students who were taken with the disease in many cases had no connection whatsoever with the other fraternity houses, either through their room-mates or otherwise. Another source of possible infection was suggested in a lot of new football suits which had recently been purchased, and which had been thought to have given rise to one or two cases of blood-poisoning. Inquiry, however, soon showed that most of the students who were sick had nothing to do with the football suits, and they were of necessity ruled out.

Naturally, one of the first objects of suspicion, after the disease had been located among the members of the three fraternities, was the table of the clubs. An examination was immediately made into the sources of supply of these three fraternities. All of them used the city water, which, of course, made it impossible to accuse the water as a source of the typhoid, there being no corresponding typhoid fever in town. The milk-supply of the three fraternities was also ruled out by several facts. The three fraternities were supplied by two different milkmen, and each of these milkmen supplied one or more of the other fraternities in college, as well as a large number of customers in town. Moreover, upon inquiry it was learned that these milkmen had not exchanged milk with each other, and that they lived at a distance of several miles from each other outside of the city. No cases of typhoid fever could be located in or near either of the milk-farms as having occurred within the last six months. It was, therefore, impossible to accuse the milk. In the same way all the other articles of food used by the fraternities were investigated, without success. The three fraternities did not have the same grocer, nor the same butcher, nor the same butter supply, nor did they obtain fruits from the same sources; and whenever, in regard to any article of food, it was found that there was a point of likeness between the three fraternities, it was found at once that the other fraternities in college shared with them in having the same source of supply. After carefully inquiring into every article of diet used on the ordinary table, it was found necessary to exclude the table as a source of infection. The attempt was then made to find some special, unusual article of food that had been used during the fall by the three fraternities, but it was impossible to do so.

When the dates of the outbreak above given are considered, it will be seen that they have themselves almost conclusively pointed to one single source of infection that had occurred in these three fraternities at a date something like two weeks earlier than October 20th. The period of incubation of typhoid fever is known to be from about eight days to about twenty-eight days, and all of the cases came in such close connection with each other as to indicate almost beyond question that they were due to one single source of infection, that occurred within two weeks prior to October 20th. On October 12th all of the fraternities in college held their annual initiation, followed by an initiation supper, and suspicion was soon thrown upon these suppers. The date of the suppers was exactly such as would be needed to explain the outbreak, and as soon as it appeared that new cases diminished after November 1st, these suppers became the most probable source of infection. When the initiation suppers were taken into consideration, one of the three exceptions above noticed disappeared, because one of the men who did not belong to the college fraternities had attended one of the three initiation suppers. An examination of the bills of fare at the sup-

pers in question was therefore instituted. It was found that nearly every article of food must be excluded, on the same grounds as the articles of food at their ordinary table. Their milk, their water, their ice, their ice cream, their fruits, their celery, and in fact nearly all other articles of diet, they either did not obtain from the same source, or obtained them from a source which supplied every other one of the seven college fraternities as well as the people in town. There was found, indeed, to be but four points of union between the three fraternities. One was the celery used in the salad, a second a small amount or fruit, a third some ham, and the fourth the oysters which were eaten. The celery, the ham and fruit, however, were from sources which supplied other clubs and a large part of the townspeople, and could, therefore, not have been the cause of the special infection confined to these three fraternities.

As soon, however, as it was found that the three fraternities each ate raw oysters from the same oyster dealer, the problems began, one after the other, to be solved. It was found that none of the other four fraternities ate these raw oysters. Two of them ate no oysters, a third ate oysters which, however, had been cooked, and the fourth obtained oysters from an entirely different source. Nor could it be learned that the lot of oysters had been used raw to any extent among the people in town, most people cooking their oysters. Another one of the above-mentioned exceptions was also explained at once, because the student, upon being questioned, stated that about the time of the initiation suppers he had eaten of the raw oysters in the store of the oyster dealer. The oysters in question were served at each fraternity on the half-shell, at the beginning of the supper, and it was, therefore, almost certain that nearly every person who attended the banquet ate of them. Correspondence and questioning, however, were immediately instituted, which resulted in tracing in this way a connection between every student who was suffering from typhoid and these oysters, with one doubtful exception of a student who has not yet been personally questioned. It was learned also that there were in attendance upon these three suppers, in addition to the students in the college, a considerable number of alumni from out of town and five students from Yale College. Letters were immediately written, therefore, to all of these persons to learn if they had eaten of the raw oysters, and whether they had suffered from any febrile disturbances. It must be remembered that the alumni were, as a rule, considerably older than the students, and it was, therefore, to be expected that the alumni would be more likely to be exempt from the disease than the students themselves. From twenty responses received from the alumni it was found, however, that there were two cases of genuine typhoid fever, which had developed simultaneously with those in the college, and that there were three other cases of sickness which had not been regarded as serious. These might or might not have had some connection with the banquet in question, though it is quite doubtful. Of the five students in Yale College, two were taken with typhoid symptoms at just four weeks after the banquet. Both of them developed into severe cases of typhoid fever. In regard to these two cases at Yale, it should, however, be noted that they appeared quite late, indeed four weeks after the supper had been held; and although four weeks is not too long a period of incubation to be possible, still it is unusual. They developed, however, at exactly the period that the last case in Wesleyan made its appearance. It is also a fact that there were two other cases of typhoid fever in Yale College that certainly had no connection with these banquets or these oysters, and it is therefore not certain that these two cases are to be attributed to these banquets. It is, however, a remarkable coincidence that of four cases of typhoid at Yale two should have been those who attended the banquet at Middletown and ate of the oysters in question, and that these two should have developed within the four weeks following the banquet. It is therefore at least probable that these cases were due to the same cause.

It will be seen that as soon as the oysters were accused of the trouble two of the three cases above mentioned of typhoid occurring outside the fraternities were at once explained. The fourth case remained isolated. This case was a member of the faculty, who had not attended either of the banquets. He was taken with a slight

found to be defective in at least one case, in the other houses it was in first-class condition. It was hardly possible to accuse the plumbing, however, inasmuch as the three clubs afflicted were situated at a distance of half a mile from each other and were connected with different sewers. The probability that these three houses should have been defective in their plumbing at the same time was very remote, and their connection with different sewers, together with the absence of typhoid in the city, made it impossible to accuse the plumbing. The possibility of transference of the disease from house to house was also considered, an attempt being made to find some early case which could possibly have been a source of infection to the other houses. But this proved futile. There were no early cases, for almost at once, upon October 20th, two or three cases developed simultaneously, and of course this made it impossible to explain the epidemic by personal contagion. It was found, moreover, that the students who were taken with the disease in many cases had no connection whatsoever with the other fraternity houses, either through their room-mates or otherwise. Another source of possible infection was suggested in a lot of new football suits which had recently been purchased, and which had been thought to have given rise to one or two cases of blood-poisoning. Inquiry, however, soon showed that most of the students who were sick had nothing to do with the football suits, and they were of necessity ruled out.

Naturally, one of the first objects of suspicion, after the disease had been located among the members of the three fraternities, was the table of the clubs. An examination was immediately made into the sources of supply of these three fraternities. All of them used the city water, which, of course, made it impossible to accuse the water as a source of the typhoid, there being no corresponding typhoid fever in town. The milk-supply of the three fraternities was also ruled out by several facts. The three fraternities were supplied by two different milkmen, and each of these milkmen supplied one or more of the other fraternities in college, as well as a large number of customers in town. Moreover, upon inquiry it was learned that these milkmen had not exchanged milk with each other, and that they lived at a distance of several miles from each other outside of the city. No cases of typhoid fever could be located in or near either of the milk-farms as having occurred within the last six months. It was, therefore, impossible to accuse the milk. In the same way all the other articles of food used by the fraternities were investigated, without success. The three fraternities did not have the same grocer, nor the same butcher, nor the same butter supply, nor did they obtain fruits from the same sources; and whenever, in regard to any article of food, it was found that there was a point of likeness between the three fraternities, it was found at once that the other fraternities in college shared with them in having the same source of supply. After carefully inquiring into every article of diet used on the ordinary table, it was found necessary to exclude the table as a source of infection. The attempt was then made to find some special, unusual article of food that had been used during the fall by the three fraternities, but it was impossible to do so.

When the dates of the outbreak above given are considered, it will be seen that they have themselves almost conclusively pointed to one single source of infection that had occurred in these three fraternities at a date something like two weeks earlier than October 20th. The period of incubation of typhoid fever is known to be from about eight days to about twenty-eight days, and all of the cases came in such close connection with each other as to indicate almost beyond question that they were due to one single source of infection, that occurred within two weeks prior to October 20th. On October 12th all of the fraternities in college held their annual initiation, followed by an initiation supper, and suspicion was soon thrown upon these suppers. The date of the suppers was exactly such as would be needed to explain the outbreak, and as soon as it appeared that new cases diminished after November 1st, these suppers became the most probable source of infection. When the initiation suppers were taken into consideration, one of the three exceptions above noticed disappeared, because one of the men who did not belong to the college fraternities had attended one of the three initiation suppers. An examination of the bills of fare at the sup-

pers in question was therefore instituted. It was found that nearly every article of food must be excluded, on the same grounds as the articles of food at their ordinary table. Their milk, their water, their ice, their ice cream, their fruits, their celery, and in fact nearly all other articles of diet, they either did not obtain from the same source, or obtained them from a source which supplied every other one of the seven college fraternities as well as the people in town. There was found, indeed, to be but four points of union between the three fraternities. One was the celery used in the salad, a second a small amount or fruit, a third some ham, and the fourth the oysters which were eaten. The celery, the ham and fruit, however, were from sources which supplied other clubs and a large part of the townspeople, and could, therefore, not have been the cause of the special infection confined to these three fraternities.

As soon, however, as it was found that the three fraternities each ate raw oysters from the same oyster dealer, the problems began, one after the other, to be solved. It was found that none of the other four fraternities ate these raw oysters. Two of them ate no oysters, a third ate oysters which, however, had been cooked, and the fourth obtained oysters from an entirely different source. Nor could it be learned that the lot of oysters had been used raw to any extent among the people in town, most people cooking their oysters. Another one of the above-mentioned exceptions was also explained at once, because the student, upon being questioned, stated that about the time of the initiation suppers he had eaten of the raw oysters in the store of the oyster dealer. The oysters in question were served at each fraternity on the half-shell, at the beginning of the supper, and it was, therefore, almost certain that nearly every person who attended the banquet ate of them. Correspondence and questioning, however, were immediately instituted, which resulted in tracing in this way a connection between every student who was suffering from typhoid and these oysters, with one doubtful exception of a student who has not yet been personally questioned. It was learned also that there were in attendance upon these three suppers, in addition to the students in the college, a considerable number of alumni from out of town and five students from Yale College. Letters were immediately written, therefore, to all of these persons to learn if they had eaten of the raw oysters, and whether they had suffered from any febrile disturbances. It must be remembered that the alumni were, as a rule, considerably older than the students, and it was, therefore, to be expected that the alumni would be more likely to be exempt from the disease than the students themselves. From twenty responses received from the alumni it was found, however, that there were two cases of genuine typhoid fever, which had developed simultaneously with those in the college, and that there were three other cases of sickness which had not been regarded as serious. These might or might not have had some connection with the banquet in question, though it is quite doubtful. Of the five students in Yale College, two were taken with typhoid symptoms at just four weeks after the banquet. Both of them developed into severe cases of typhoid fever. In regard to these two cases at Yale, it should, however, be noted that they appeared quite late, indeed four weeks after the supper had been held; and although four weeks is not too long a period of incubation to be possible, still it is unusual. They developed, however, at exactly the period that the last case in Wesleyan made its appearance. It is also a fact that there were two other cases of typhoid fever in Yale College that certainly had no connection with these banquets or these oysters, and it is therefore not certain that these two cases are to be attributed to these banquets. It is, however, a remarkable coincidence that of four cases of typhoid at Yale two should have been those who attended the banquet at Middletown and ate of the oysters in question, and that these two should have developed within the four weeks following the banquet. It is therefore at least probable that these cases were due to the same cause.

It will be seen that as soon as the oysters were accused of the trouble two of the three cases above mentioned of typhoid occurring outside the fraternities were at once explained. The fourth case remained isolated. This case was a member of the faculty, who had not attended either of the banquets. He was taken with a slight

fever, and inasmuch as it appeared at about the same time with the students, it was regarded as identical with the other cases. It proved, however, a very slight fever, lasting only a few days, and it is therefore at least doubtful whether it was typhoid. Whether this person ate of the raw oysters cannot be positively determined. It is a fact that raw oysters were eaten at the table where he boarded at about the time of the banquet, but as yet no positive connection between the person and these oysters has been made out. Whether, therefore, this case is to be regarded as an isolated case of fever having no connection with the others and not strictly typhoid fever, or whether it is a fact that it is also explained by some connection with the infected oysters, has not been determined.

Inquiry was made at once as to the source of the oysters, and it was learned that while they had grown in the deep water of Long Island Sound, they had been deposited in the mouth of a fresh-water creek for a day or more to freshen. This freshening, as is well known, consists of the absorption by the oysters of fresh water, which causes them to swell up and become plump. These oysters had thus been "fattened" before being sent to Middletown. Further inquiry showed that, within about three hundred feet of the place where they had been deposited, was the outlet of a private sewer coming from a house wherein were two cases of typhoid fever. The persons in question were a lady and her daughter. They were taken sick at such a period as to call in a physician for the first time October 11th, which, of course, means that the disease had been in its period of incubation for probably considerably over a week earlier. The oysters were sent to Middletown on October 10th, and therefore they were deposited at this place in exactly the time to receive contamination during the early days of these two cases of typhoid. Of those two cases one proved extremely severe, and the lady died on October 21st. In the other case the fever, after running about five weeks, disappeared and convalescence set in. It is, of course, very easy to understand that the typhoid germs could have found entrance into the oysters from this source of contamination. Now, it has been known for some time, having been shown by Foster and Freytag, that the typhoid germs will live for a long time in sea-water or, indeed, in a concentrated salt solution. Specimens of the oysters from the creek, however, were put into the hands of Dr. Foote, of Yale College, who soon showed that if the typhoid germs were forced in between the two valves of the shell they would remain alive in the oyster for a time sufficient to enable the oyster to be carried to Middletown and to be used at the initiation banquets. Whether or not they will grow and multiply in oysters has not yet been positively determined.

Shortly after the oysters had been placed under suspicion it was learned that there were at Amherst College several cases of typhoid fever. Correspondence was instituted which resulted in showing that at Amherst there had been an initiation supper on the night of October 12th. Most of the cases of typhoid at Amherst occurred among the members of one fraternity, who, as at Wesleyan, neither roomed nor boarded together. They, however, had attended the initiation supper on October 12th, had eaten of raw oysters at the supper, and inquiry showed that these raw oysters also came from the same place as the Wesleyan oysters, and had been fattened in the mouth of the same creek. As at Wesleyan, certain wells were first placed under suspicion, but examination showed them to be good. While, of course, this did not conclusively demonstrate that the cases at Amherst were due to the same source of infection as that at Wesleyan, it rendered it at least probable.

The facts above related, it will be seen, point with conclusive force to the oysters as the cause of the typhoid outbreak. The dates of the outbreak, October 20th to November 8th, plainly point to one source of infection about October 12th. The fact that two cases of genuine typhoid developed at the same time among the alumni, and that two others appeared also among Yale students, none of whom have had connection with the three fraternities later than the initiation supper, or before that time, plainly demonstrates the initiation supper on October 12th as the time of the infection. At these initiation suppers only one article of food or drink was used which was not used by the other fraternities in college and by the

people in town in general. That one article of food, the raw oysters (not eaten raw by people in town in general), was learned to come from a place where it was certainly subjected to a probable contamination of typhoid fever from two severe cases of the disease. The use of raw oysters from the same locality elsewhere has been found, at least in one case, to have been followed by a similar outbreak as occurred in Wesleyan. These facts taken together leave no possible doubt that the Wesleyan typhoid fever was caused by the oysters in question.

It must not, however, be inferred that because the lot of oysters supplied at these initiation suppers was infected, therefore that all the oysters from the same locality would be thus infected. The public press has certainly exaggerated the condition of affairs. The oysters from the same locality were widely used in Connecticut, and doubtless in many cases have been eaten uncooked. There has been, it is true, quite a little typhoid fever in Connecticut during the past month, but it has not been possible thus far to trace very much of it to the eating of raw oysters. The probability is that the oysters fattening in the locality in question would not, as a rule, be contaminated, but that it would only be an exceptional condition that would produce the result. It would be necessary that they should be lying in this place at just the period when the typhoid germs were swept by the currents or eddies from the sewer over the oyster-bed; and such a condition, even though there might be continued cases of typhoid in the course of the sewer, would doubtless not by any means be a constant one. Oysters, as a rule, are said to open their shells on flood-tide rather than ebb-tide, and this would, of course, make it more difficult for them to be contaminated by sewage from sewers above them on the creek. While this would by no means make the chance of contamination impossible, it would certainly render it less. It is not to be supposed, therefore, that the oysters deposited in the creek for fattening would all, or indeed many of them, become contaminated by the typhoid material, but that only exceptional conditions would produce the result. Where a private sewer containing typhoid excreta opens in the vicinity of such an oyster-bed, the danger must certainly be considerable. Where the typhoid material is mixed in the city sewers with the large amount of sewage and is subsequently diffused through a considerable body of salt water when the sewer empties into the sea, the danger of oyster contamination must be considerably less. But there must be danger to public health from oysters fattened in any fresh water in the vicinity of sewage.

Doubtless many cases of mysterious typhoid have been due to such a cause. To trace these cases is a matter of extreme difficulty. The peculiar conditions which have occurred here have been such, however, as to bring the matter into clear light, and to throw with certainty blame of typhoid distribution upon a source which has for some time been suspected, but not demonstrated. That the practice of fattening oysters in the mouth of rivers and in the vicinity of sewers is dangerous to the public health, is beyond question shown by the combination of conditions which have made it possible to trace the Wesleyan typhoid outbreak to the eating of a lot of infected raw oysters.

Hopeful.

"How is your son getting along in college?" asked Farmer Corntossel's neighbor.

"Purty well in some ways. I don't know how he's doin' in his studies. But from his last photograph I jedge he's discovered a hair tonic thet'll make his fortune."—*Washington Star.*

WATTS—Tebson must be awfully afraid of his wife. He is always telling us how she will give him fits if he don't hurry home. Potts—That's the best sign in the world that he is not afraid of her at all. The man who is bossed by his wife never says a word about it.—*Indianapolis Journal.*

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

THE AMERICAN JOURNAL OF OBSTETRICS for November.

Inflammatory Disease of the Uterus and Appendages and of the Pelvic Peritoneum

is the subject of a series of papers by well-known operators. These papers were read in a discussion before the American Association of Obstetricians and Gynecologists, at Toronto, September 20, 1894, the introductory remarks on the subject being furnished by William Warren Potter, M.D., of Buffalo, N. Y. In this paper the author reviews the history of the knowledge of inflammatory disease in the pelvis and urges that the profession be not deceived by the so-called conservative teaching of the present day which would leave organs that have ceased to perform their physiological functions and have become a menace to the woman's well being.

The clinical history of the disease is well pictured by Charles A. L. Reed, M.D., of Cincinnati, Ohio; while the causation and pathology falls to the share of L. S. McMurtry, M.D., of Louisville, Ky. Pelvic inflammation originates, he says, practically without exception, from septic infection. This may be specific or traumatic, including among traumatic causes the wounds of childbearing and abortion. Puerperal infection exceeds all other etiological factors in this disease. There is abundant evidence that many puerperal women are infected with gonorrhœa and that both the puerperal and specific causes may coexist in the same individual. A different class of traumatic infection is that of certain surgical operations and manipulations upon the uterus. Such are the injury and contamination of sponge tents, of steel dilators, and operations upon the cervix and within the uterine cavity. It is not the traumatism *per se* which begets the inflammatory process; it is the admission of septic material. The inflammation is prevented by a healthy, clean mucous membrane and a proper aseptic condition of instruments.

The se ction on diagnosis and prognosis is contributed by J. F. W. Ross, M.D., of Toronto, Can. He admits that the diagnosis of the cases in which there is but little to be felt in the pelvis is difficult, and such cases are likely to be mistaken for cases of so called ovaritis and for cases in which the ovaries are tender owing to some anemic or other condition of the system. Neurotic women and anemic girls frequently suffer from this ovarian tenderness. Such tenderness exists without the presence of any actual disease, and these cases should never be operated upon. If they are observed closely for a time no acceleration of pulse or rise in temperature will be noticed. The pus tube may be mistaken for a fibroid, as has happened to the author himself. During the development of pus tubes patients are usually supposed to be suffering from typhoid or malarial fever. The diagnosis in such cases should be made by the expert finger in the vagina. This shows the importance of the vaginal examination in all cases of prolonged fever. While many cases of disease of the uterus and appendages do get well without operative interference, in those cases that suffer from relapses nothing will relieve them but the removal of the tubes and ovaries. In cases suffering from large pus tubes cure is dependent on the removal of such tubes. The drainage of pus tubes the author regards as bad practice. What applies to the pus tubes applies equally well to the septic hematoma of the ovary and ovarian abscess. The author asserts that for pus tubes interfering with health and causing recurrent attacks of inflammation there is but one treatment, namely, removal by surgical means, and the patients do not become unsexed.

When inflammation of the uterine appendages kills it does so for want of operation, but it kills slowly and before producing death causes an enormous amount of suffering. A condition of chronic septicemia sets in, the patient becomes emaciated and confined to bed, bedsores form and she slowly but surely dies.

The subject of treatment is discussed by Marcus Rosenwasser, M.D., of Cleveland, Ohio. This he divides into the treatment of acute and chronic peritonitis, medical and surgical. The removal of the immediate cause, the cleansing of the parts, free purgation, rest in the horizontal position, with hot fomentation or ice-bag to the hypogastrium, are the essential features of the medical treatment of acute peritonitis. Stimulants and strychnia may be needed if the pulse is rapid and weak. Some cases, especially neurotics, require opiates from time to time for the relief of pain, which are best given by suppository or subcutaneously. Opiates should be used sparingly and should be early discontinued. Hot vaginal douches may be used if well borne, not otherwise. Small blisters to the inguinal regions are of no value. Frequent repetition of saline laxatives is followed by relief of pain. The bromides serve a good purpose in allaying reflex nervous manifestations. The giving of iodides and mercurials with the idea of dissolving exudates is decidedly wrong, since the plastic material is thrown out by nature as a bulwark against general peritoneal invasion.

In regard to the surgical treatment, curetting and free drainage of the uterine cavity before infection has spread to the tubes or beyond will in many cases limit or abort the inflammation within the uterus. But when the appendages have been drawn into the inflamed area, the procedure is of questionable utility and is often harmful.

Abdominal section is called for when symptoms point to the formation of abscess either within a pelvic organ or within a circumscribed space in the pelvic cavity. Should such abscess rupture, section is indicated if it can be performed immediately or within the first few hours before general inflammation has developed. In the latter event the results are not encouraging. After general peritonitis has set in, with a small and rapid pulse, vomiting and increasing tympanites, the author inclines to active stimulation and the pushing of strychina to the point of toleration rather than operative interference.

In the chronic pelvic peritonitis the medical treatment consists in rest in bed with attention to the bowels, to feeding and to hygiene. Boroglyceride or ichthyol tampons of lamb's wool, by supporting the pelvic diaphragm and depleting the blood-vessels, hasten recovery in some cases. Gentle pelvic massage may be of value in softening adhesions and may thus aid in the reposition of fixed organs. Local electricity may be of temporary benefit. As a resolvent of exudates it has proven a failure in the author's hands after repeated and patient trial.

While curetting, when carefully done, may be of benefit in some cases, abdominal section is the recognized surgical treatment for suppurating appendages. The uterus should be removed if it is also infected or honeycombed with pus. The sinuses and fistulæ that remain after the discharge of so-called pelvic abscesses and resist efforts to cure by drainage and injection of irritants may be cured by removing the cause, located in the remnants of suppurating tube and ovary.

The treatment of inflammation of the uterus and appendages is also discussed by A. Vander Veer, M.D., of Albany, N. Y., who agrees very closely with Dr Rosenwasser. J. Henry Carstens, M.D., of Detroit, Mich., contributes further remarks on the treatment, and urges that a microscopical examination be made in every case of leucorrhœa with burning micturition of sudden onset, to determine whether of gonorrhœal origin or not. If gonorrhœal, it should be treated not by douches but by thoroughly cleaning out the vagina, the uterus and cervix and applying iodine, corrosive sublimate and other germicides thoroughly and effectively.

After abortion the author believes in cleaning out the cavity of the uterus with a dull curette and applying pure carbolic acid. The author sums up his paper as follows:

1. Let the general practitioner most conscientiously and carefully treat gonorrhœal infection in women.

2. Let the family physician and obstetrician most carefully manage confinements aseptically, and in the treatment of miscarriages be most thorough and not trust the *vis medicatrix naturæ*, but carefully clean out the uterine cavity.

3. Girls or young women who have leucorrhœa and pelvic pain, the result of accident or not, should be most carefully and early treated before mischief has been done.

4 In cases of acute inflammation judge each case by itself. If the symptoms are mild palliative treatment with absolute rest will be proper, and an operation can be performed later.

5. Cases of six or eight weeks' standing with sepsis should be operated on promptly.

6. When operating try and remove all diseased tissues if you expect your patients to get well promptly and perfectly. If you cannot and a second operation is necessary, tell your patient or the friends immediately, otherwise you will bring abdominal surgery into bad repute.

The remaining paper of the group, "Various Modes of Treatment," by Joseph Price, M.D., of Philadelphia, appeared in the issue of THE MEDICAL AND SURGICAL REPORTER for November 24th, page 709.

Francis Foerster, M.D., Professor of the Diseases of Women to the New York Post-Graduate Medical School and Hospital, etc., continues his articles on the

Comparative Microscopical Studies of the Ovary,

this paper being concerned with the stroma of the ovary. As the result of his studies he lays down the following corollaries:

1. In accord with W. His and others, the ovary must be considered an erectile organ in whose cortex the smooth muscle fibers largely predominate over the connective tissue.

2. The medulla of the ovary is mainly composed of fibrous connective tissue holding comparatively few bundles of smooth muscle fibers.

3. In the cortex of the human ovary the bundles of smooth muscle fibers interlace in an almost vertical sagittal and frontal direction.

4. In the cortex of the ovary of the guinea-pig the smooth muscles exhibit a plexiform arrangement, also to be seen in the ovary of the cat and ewe.

5. The arteries of the medulla of the human ovary have a markedly tortuous course. Their muscle coat is liable to a hyaline infiltration and to endarteritis obliterans.

6. In the medulla of the ovary of the cow, the ewe and the sow peculiar vascular tufts are invariably met with, consisting of arteries, veins and capillaries whose walls are changed into myxomatous tissue.

7. Within such vascular tufts almost always an effusion of serum or lymph is met with, often to a considerable extent. These effusions are probably due to a rupture of lymphatics occurring by the methods of slaughtering the animals.

8. The arteries, and probably also the veins, in the medulla of the ovary of the cow, ewe and sow are frequently found changed to a myxomatous tissue either holding trabeculæ of muscle fibers or consisting of purely myxomatous tissue. This change not infrequently leads to an obliteration of the blood-vessels named.

J. F. W. Ross, M.D., of Toronto, Can., contributes an article entitled

Personal Experience With Pus Tubes.

He states that he has met with four varie-

ties, namely, intratubal abscess, intraovarian abscess, intraligamentous abscess, and extraperitoneal abscess (that is, an abscess entirely outside the tissues forming the pelvic contents). The latter variety may be cured by puncture and drainage. The third variety, or intraligamentous abscess, must be opened and drained, but if accompanied by a pus tube that is not removed the abscess may remain uncured until the pus tube is removed. The second variety will occasionally cure itself by perforating downward and discharging its contents, but the patient will not remain well while the contracted and disorganized ovary is left in situ. The intratubal abscess should always be treated by removal of the tube.

In looking back over his records, the author finds that the fatal cases were chiefly those in which gonorrhœa was contracted but a short time previous to operation, and he believes that it is not wise to operate on these cases too soon after the primary infection. It is better to wait till the pus has become to a certain extent sterile and until the poisonous germ has become attenuated. The author is also firmly convinced that none but those who have had the advantage of a special training in this department of surgery should undertake the operations for the relief of the cases under discussion.

The author is a firm believer in the efficacy of the drainage tube, and it is his practice to leave it in for a period of about eight days, at the end of which time it is replaced by a rubber tube. He thinks that the danger of infection of the peritoneum through the drainage tube is a myth if the tube is properly cared for. Moreover, he does not think that the recent suggestions to examine the pus from a pus tube or suppurating ovary microscopically and judge from the result of the necessity for drainage is practicable in the work of a majority of operators, and he therefore thinks it best to adopt drainage in all doubtful cases.

Flushing, to be of any service, must be thorough, and a large quantity of water must be used. Such a stream of water should be used as will float out clots and pieces of *debris* as well as remove pus.

The ligation of the pedicle is a matter of great importance, and the author does not approve of curetting the stump of the tube to remove all diseased tissues. By so doing the stump is made conical and there is greater opportunity for the ligature to slip. The tissue of a pus tube, like the tissue of a fibroid, has a tendency to shrink; the ligatures should therefore be applied very tightly.

The author suggests that a drainage tube be passed into the bottom of the pelvis during the interval of time that is occupied by passing the sutures, as in this way the amount of hemorrhage can be determined and steps taken to arrest it if excessive.

Appended to the paper is a table of the results of seventy-four operations.

The Present Status of the Treatment of Pelvic Inflammation

is the title of a paper by Walter B. Dorsett, M.D., Professor of Obstetrics, Beaumont Hospital Medical College, St. Louis, Mo. The following are his deductions, which are in marked contrast to the opinions of the writer of the previous article:

1. Pus in quantities is hard to deal with down in the pelvis in laparotomy cases, and if possible should be evacuated prior to taking out the tubes and ovaries, either through the *cul-de-sac* of Douglas or, if between the layers of the broad ligament at the side of the uterus, do your laparotomy at some future time.

2. Pus sacs in the tube near the uterine end of the tube can be evacuated through the uterus by packing the horn.

3. Parametritis, or cellulitis of the ancients, is, except in rare instances, a secondary trouble, due to a foul uterine cavity. Clean out the cavity and stop the source of poin poison, and you do the best thing possible to be done.

The remaining papers in this issue are "Total Extirpation by the Vagina for Lesions of the Uterine Appendages," by Charles Jacobs, M.D., of Brussels, Belgium, in which the procedure is strongly advocated; "Treatment of Distention of the Fallopian Tubes without Laparotomy and Removal," by Frank A. Glascow, A.B., M.D., Professor of Clinical Gynecology, St. Louis Medical College, in which the author advises dilatation of the uterus (by means of sterilized slippery-elm tents) which is kept up for several days, at the end of which time there is usually a discharge of pus and relief of symptoms. If, when the uterine canal is large enough to admit the finger, there is no discharge of pus, the author anesthetizes the patient and curettes the uterus. The author reports two cases relieved in this manner and one in which relief did not follow and where he was obliged to open the abscess, which was in the ligament.

Chloral Hydrate for Scarlet Fever.

Dr. James C. Wilson, in a paper read before the Pan-American Medical Congress, gave as his experience that chloral in doses of two or three grains in a teaspoonful of sirup every three or four hours exercises a powerful influence in this disease. Given thus it is to a high degree diuretic, controls the nervous symptoms, and to some extent antiseptic and tends to diminish blood pressure and lower the temperature. He has employed it for over ten years with more satisfactory results than from any other method of treatment.—*Phila. Polyclinic.*

Permanganate of Potash as an Antidote to the Cyanides.

Dr. J. V. Kossa, from experiments on animals, claims that the permanganate of potash is an efficient antidote to hydrocianic acid and the cyanides. A dose of over ten times greater than the fatal one was given to rabbits and immediately followed by the permanganate; no symptoms of poisoning followed. The potash salt oxidizes the poisonous compounds into innocuous preparations

PERISCOPE.

MEDICINE.

Value of Opium in the Laryngeal Stenoses of Children.

Dr. Carl Stern (*Ther. Monat.*) recalls the well-known fact that the difficulty in breathing in stenosis of the larynx in children is greatly aggravated by sleeplessness and fright. For this reason he has been led to treat these cases with opium, and his results have been so gratifying that he believes the remedy should receive more extensive employment. He uses it in cases—whether in diphtheria or without existing throat affection—in which the hoarseness, the barking cough, the stridor, the cyanosis, and finally the sucking in of the xiphoid process and lateral portions of the thorax point unmistakably to stenosis of the larynx. He reports several cases in which the use of opium averted an apparently necessary tracheotomy. Stern gives from two to five drops of the tincture of opium, according to the age of the child and the intensity of the symptoms, the dose being renewed according to the result obtained.

Relapses in Typhoid Fever.

Dr. Hugh U. Stewart contributes an instructive paper on this subject to the *Practitioner*. The writer defines a relapse as a second attack of typhoid fever, with a repetition of all the phenomena of the first illness, occurring in a patient who has become or is just becoming convalescent from the primary attack. The clinical history of 50 consecutive cases collected from the records of Guy's Hospital showed that men were especially liable to relapses, 31 of the patients being males and only 19 females. Age appears to have no special influence, relapses simply occurring most often at that period of life at which typhoid fever is most common.

The interval of apyrexia between the primary attack and the relapse was, in the majority of cases, from five to eight days; but it may vary from one up to twenty-four days. In cases in which there were two relapses, the usual interval between the first and second relapse was at least double that between the first attack and the first relapse. The relapse is nearly always of shorter duration than the primary attack; and in cases with two relapses the second was never as long as the first.

Perhaps the most important clinical feature in these cases was the state of the bowels. Constipation was present in 62 per cent., the bowels were regular in 20 per cent., leaving only 18 per cent. in which there was more or less diarrhœa. These figures seem to justify the view that constipation has an important relation to the occurrence of relapses.

In order to study the pathology of relapses, Dr. Stewart collected 40 fatal cases from various sources. These cases show, without a doubt, that there is an important difference in the seat of ulceration in primary attacks and in relapses. In 34 of these 40 cases, or 85 per cent., the large intestine contained recent ulcers and the small intestine contained healed ulcers; while in 65 cases of single attacks collected for comparison, 48, or 75 per cent, had the large intestine quite healthy, but the small intestine showed recent ulcerations. The author therefore holds that a relapse is due to a reinfection of the large intestine by sloughs derived from some part of the small intestine above.

It is generally agreed that a fatal termination to a relapse of typhoid fever is very rare. This is easily explained, according to Dr. Stewart, when we remember, first, that the relapse, owing to the acquired partial immunity, is not so severe as the primary attack, and, secondly, that the large intestine, which is the chief seat of ulceration in relapse, is thicker than the small. Thus the very important danger of perforation is to a large extent removed in a relapse, and we find accordingly that the prognosis, far from being worse, is considerably better than that of a single attack.

Medical Antisepsis.

M. Petresco, of Bucharest (*Gaz. des Hop.*), reports results which he has obtained by medical antisepsis which he has largely used as a therapeutic measure. He has employed nearly all the antiseptics in use. His conclusions are as follows:

1. A local medical or general antisepsis at a distance on the histological elements and on the pathogenic germs or on their toxines can be obtained which is analogous to local surgical antisepsis.

2. There are several chemical substances (fixed or volatile) which upon absorption can, even in remote parts, kill or attenuate certain pathogenic micro-organisms.

3. There are some medicaments which neutralize or modify chemically the toxines of pathogenic germs.

4. The best therapeutic agents to produce medical antisepsis are the products, more or less condensed, of the aromatic series, such as the essences. The essences are the antiseptics *par excellence* as much in medicine as in surgery. It is by the essences or their vapors that impregnation is obtained, a modification, more or less profound, of the organism, and in consequence a medical immunity. There is created a medical sterilization of the interior tissues analogous to the sterilization *in vitro* in a culture. By this sterilization or antisepsis of the interior microbe or ptomaine, auto-intoxication is prevented in sufferers from contagious diseases.

5. Medical antisepsis should be utilized in nearly all internal diseases of a microbic nature, as it has been utilized in the external parasitic diseases.

6. To establish the basis of medical antisepsis we must have a therapeusis which will act as a microbocide or destroy toxines or ptomaines.

A Cause for Baldness.

Dyspepsia is not only one of the most common diseases, but it is also one of the most common causes for the loss of hair. Nature is very careful to guard and protect and supply the vital organs with the proper amount of nutriment, but when she cannot command a sufficient quantity of blood supply for all the organs she very naturally cuts off the supply of parts the least vital, like the hair and nails, so that the most important organs, like the heart, lungs, etc., may be better nourished and perform their work more satisfactory. In cases of severe fevers one can readily see how nature economizes. If one will examine a hair very closely from the beard or head it will be seen that it gives somewhat of a history of an individual during the time it was growing. It will be observed that it shows attenuated places, showing that at some period of its growth the blood supply was deficient from overwork, anxiety or under-feeding. Speaking of dyspepsia being one of the most common causes of alopecia, I will add that a very common cause of indigestion is irregularity of meal-hours. The human system seems to form habits, and it performs its functions to a great measure in accordance with the habits formed. This seems to be particularly so in regard to eating, and you might say drinking too. Your stomach gets into the habit of accepting your meals at a certain hour every day, and at that hour it is ready for it. If you, however, take meals at irregular hours you take your stomach by surprise, and it does not know when to expect a meal, and it is not in that state of readiness for prompt and perfect performance of its work. Be more careful about what you eat, when you eat it, and you will have less dyspepsia and fewer bald heads.—*Ed. Charlotte Med. Jour.*

Malignant Lentigo in the Aged.

Hutchinson describes a singular affection, malignant lentigo, which begins as a brownish or black spot and which ends in the production of malignant tumor. The disease begins spontaneously or follows a lesion of the skin. In the four cases reported by Dubreuihl it was situated on the left side at the upper part of the cheek, on the eyelid, or even on the conjunctiva.

It occurs as a simple pigmentation without projection or thickening of the skin, and forms an irregular spot varying from sepia brown to black in color. It persists for ten to twenty years, remaining absolutely stationary or varying in tint, extent, sometimes disappearing, leaving the skin absolutely normal. At a given moment there appears on the spot or in its vicinity a malignant, ulcerating tumor, vegetating, bleeding, rapidly increasing in size—sometimes melanotic. It is recurrent, either at the same place or in the ganglions, presenting at each recurrence more malignancy and becoming melanotic. Histologically it resembles melanotic cancer, built up of large epithelioid cells, loosely connected, without stroma, and infiltrating its surroundings.—*Times and Register.*

Ringworm of the Scalp.

Hartzell (*Arch. of Ped.*) has the hair cut short and the following ointment rubbed into the diseased portions of the scalp once a day with considerable friction; Beta naphthol, 1 dram; petrolatum, 7 drams. In addition, the entire scalp is thoroughly washed every second day with hot water and a superfatted soap containing sulphur and salycilic acid. Unless the applications are well rubbed in to the hair follicles good results are not to be hoped for, and the treatment should be continued some time after apparent recovery.

Strychnia in Obstetrics Practice.

Duff (*Jour. of the Am. Med. Ass'n*) advises the use of strychnia in doses of one-sixtieth to one-thirtieth of a grain three times daily during the latter part of pregnancy, and believes by following this practice that the indications for instrumental delivery are less frequent, and ergot will only occasionally be called for during or after the third stage of labor. He does not offer this as a routine treatment, but as indicated in a large number of cases.

Apomorphine as an Expectorant.

Carmichael (*Cin. Lancet-Clinic*) says of this drug: "As an expectorant, in doses ranging from one-twentieth to one-sixtieth of a grain, great relief may be obtained in cases of bronchitis, trachitis and catarrhal pneumonia. From the fact that it produces emesis by its action through the spinal nerve centers, and not by irritation of the mucous membrane, it is a preferable remedy where we have inflammatory conditions of the stomach and emetics are indicated."

Whooping-Cough Cut Short.

The *Illustrated Medical Journal* says Dr. Moncoro treats pertussis with a 10 per cent. solution of resorcin, applying the solution every two hours to periglotteal region with a brush. Application is made four or five times at each sitting. The theory is that the disease is due to micro-organisms and affects primarily the larynx. Cultures of the micro-organisms have been destroyed by the smallest amount of resorcin.

Cold Water as an Antipyretic.

Dr. Fisher has arrived at the following conclusions:

1. That cold water is the best antipyretic used to-day.

2. That it is easily obtainable and is therefore adapted to all classes of cases, both rich and poor.
3. The mode of application is so simple that it adapts itself to the hospital and equally as well to private practice, and can be applied without any distinct training.
4. Cautiously given it stimulates.
5. Carelessly used and longer than required it depresses and will produce subnormal temperature.
6. That rectal temperature should be taken and the bath at once discontinued when temperature falls to 101°, as it will then continue to fall.
7. That a stimulant administered before the bath may be necessary and should be given where there is a feeble heart.
8. That the temperature indicates when to commence and when also to discontinue the hydropathic treatment.
9. Unnecessary blanketing after a bath is injurious and will produce copious perspiration, which I believe weakens the patient.
10. The temperature of the room should always be between 68° and 72°.—*Post-Graduate.*

The Cold Poultice as an Antipyretic in High Grades of Fever.

Bedford Brown, of Alexandria, Va., has used the cold poultice in his practice for the past fifteen years, with much satisfaction to himself and infinite comfort to his patients. He finds it to possess many advantages over the coal-tar antipyretics, as it never depresses the action of the heart or nervous system, but accomplishes its work speedily, easily, pleasantly, with comfort to the patient. His method of preparing the poultice is as follows: A sufficient quantity of flaxseed meal to prepare a poultice of suitable dimensions is placed in a common earthen bowl, and over this is poured boiling water, while the meal is constantly stirred with a large spoon until cooked to the consistency of soft mush. This material is then spread on a piece of soft cotton cloth, for an adult, about eighteen inches long and twelve or fourteen wide, or sufficiently long to cover the entire abdomen from the pubis upward, extending at least over half of the chest, well over the cardiac region, so as to fully cover the heart and half of the chest. This poultice is now covered with another piece of cotton of corresponding dimensions. After being spread and covered, the entire surface to be applied to the person is frequently besprinkled with ice-water until its temperature goes down to 68° or 70° F. (20° or 21.1° C.), when it is ready for application. At this point I would suggest that the poultice be not spread too thick, as in that case it would prove oppressive to the patient. The poultice thus prepared is applied over the chest from above the cardiac region to the pubis. In pneumonia of violent type, with an unyielding temperature of 104° or 105° F. (40° or 40.6° C.), frequent, hard, wiry pulse, great frequency and oppression of respiration, Dr. Brown has seen a cold poultice applied over the entire chest, extending back well over the sides, accomplish more in the reduction of temperature, of frequency of cardiac action and respiration, than all other local agents combined. If necessary the poultice should be renewed until the temperature falls to normal.—*Virginia Med. Monthly.*

A Case of Leucocythæmia Apparently Cured by Bone-Marrow.

Dr. W. G. Bigger reports a lad, aged twelve years, who for the previous six years had been under observation, suffering from splenic enlargement with anæmic symptoms, but who had previously been much relieved by treatment with arsenic and iron. Two months ago the disease acquired a more active character. The spleen became much larger and completely filled the left half of the abdomen, while at the same time there were diarrhœa, pyrexia and frequent attacks of epistaxis. He was now fed on raw bone-marrow spread on thin slices of bread. Under this treatment the improvement in the boy's condition, after the first week, was marvelous. The spleen diminished in size and the anæmia rapidly decreased. After a month's treatment the boy was reported as being better than ever before, while the spleen had receded and was at that time only felt about three inches below the ribs.

Treatment of Apparent Death by Rhythmical Traction Upon the Tongue.

The first case in which rhythmical traction of the tongue was employed at Paris to produce artificial respiration was by M. Lapicida (*La Tribune Medicale*), aided by a student.

A young woman, wishing to commit suicide, sprang into the Seine. She was seen by two sailors, who went to her rescue; after remaining for five minutes submerged, she was finally withdrawn from the river. Taken at once to the station, frictions were applied, but without success, when M. Lapicida, following the method of Laborde, began rhythmical tractions of the tongue.

At the end of five minutes a slight blowing sound was heard and respirations were established. At the same time the patient experienced a nervous crisis and objected to being resuscitated. She was placed in bed and enveloped in warm clothing. A few moments afterward she vomited freely and all danger was over.

Lapicida, who is chief of the post of the life-saving society, expressed himself as amazed at the rapidity with which the respiratory functions were restored, and resolved to employ this method in all cases which came under his care in the future.

Notices detailing the method of Laborde have been placed in the life-saving stations throughout Paris.

The Treatment of Tapeworm.

Dr. Leslie Ogilvie attributes the frequent failures in the attempt to remove a tapeworm

to a lack of attention to details in the administration of the drug used. When the purgative is given soon after the anthelmintic the worm is carried away, all but the head. In such cases it is useless to repeat the drug, as is frequently done, in a short time, as the worm offers but scanty absorbing surface and the chief effect of the drug is to poison the patient. Neither does he consider castor oil a suitable purgative to give before the administration of the anthelmintic, as there is in all probability a considerable coating of mucus about the worm which the oil does not remove. Sulphate of magnesia with tincture of jalap he considers the most efficacious preliminary purgative. He conducts his case as follows, and reports 13 consecutive cases successfully treated, 10 of which had been previously treated without result. The patient should eat less than usual for a few days before treatment, and the day before should be restricted to a milk diet with a little stimulant. At bedtime a purgative draught of sulphate of magnesia and tincture of jalap is given, and repeated at 7 the next morning if the first dose has not operated. At 8 A.M. a drachm of fluid extract of male fern is given, and at 9 o'clock a second dose. At 11 o'clock a dose of castor oil is administered; even if the worm has been passed previously, it is well to give the oil to remove any of the poison which may be left. The physician should pay a visit soon after the second dose of male fern has been given, not only to observe the patient, but to inspect all the motions, each one of which should be passed into a separate utensil. In searching for the head it is convenient and less unpleasant to use a dilute solution of permanganate of potash as a disinfectant with which to separate the worm from the feces.—*Boston Med. and Surg. Jour.*

Malarial Organisms in Enteric Fever.

After a short review of the relations existing between typhoid fever and malarial fever, and also a reference to the Woodward theory that the simultaneous presence of the typhoid-fever and the malarial-fever poisons produces a third independent or hybrid affection, called "typho-malaria," W. Gilman Thompson, of New York City, presents a detailed report of three carefully studied cases of typhoid fever, in two of which the malarial body was found and the third contained abundant malarial pigment granules. In the first case reported the plasmodium became active during the course of the disease, while in the second and third cases the malarial organism remained latent until the force of the enteric infection had been nearly expended. These cases distinctly prove that both typhoid and malarial fever may exist simultaneously, a fact that has been disbelieved by many good observers. It is also clear from the evidence presented that the combination of these two poisons does not produce a third definite disease. but that each process goes on side by side. In two of the cases the malarial poison was late it until the resistance of the body had been reduced by the typhoid poison.—*Amer. Jour. of the Med. Sci.*

DR. CHARLES HENRY BROWN, of New York, editor of the *Journal of Nervous and Mental Diseases*, says: "Where maltine with coca wine has served me best has been in cases of neurasthenia from any causes whatever. It certainly serves as a most excellent sustainer and bracer. Besides these two most necessary qualities, we are forced to believe in another in this combination, and that is the composing sedative or soothing quality which makes it a most valuable therapeutic desideratum. It does not seem to me that this sedative action depends entirely upon the coca or coca in combination with the wine. There is a conviction in my mind that maltine plays a very leading sedative part in this triple alliance."

ARMY AND NAVY.

CHANGES IN THE U. S. ARMY FROM DECEMBER 2, 1894, TO DECEMBER 15, 1894.

Leave of absence for four months on surgeon's certificate of disability, with permission to leave the Department of Dakota, is granted First Lieutenant Alexander S. Porter, Assistant Surgeon.

Leave of absence for four months, to take effect on or about January 20, 1895, with authority to go beyond the sea, is granted Captain Walter D. McCaw, Assistant Surgeon.

The leave of absence granted Captain Eugene L. Swift, Assistant Surgeon, is further extended two months.

First Lieutenant Charles E. B. Flagg, Assistant Surgeon, now on duty at Angel Island, Cal., will report in person at Fort Townsend, Washington, for temporary duty at that post.

Captain Euclid B. Frick, Assistant Surgeon, is granted leave of absence for four months.

First Lieutenant Madison M. Brewer, Assistant Surgeon, upon the expiration of his present leave of absence, will be relieved from duty at Fort Riley, Kansas, and will report for duty at Fort Keogh, Montana.

NEWS AND MISCELLANY.

Reduced Rates for Christmas and New Year's.

The B. & O. R. R. Co. announces that excursion tickets will be sold between all stations on its lines east of the Ohio River during Christmas and New Year holidays, at reduced rates, for all trains December 22, 23, 24, 25, 29, 30, 31, and January 1, 1895, valid for return passage until January 3, 1895, inclusive.—3t

ORIGINAL ARTICLES.

REMOVAL OF DISEASED APPENDAGES RESULTING FROM CLOSURE OF THE CERVIX—REPORT OF A CASE.*

THOS. LEIDY RHOADS, M.D., Boyertown, Pa.

It is a well-established fact with specialists engaged in this particular line of practice that disease of the uterine appendages is frequently traceable to minor gynecological procedures. Among the operations classified under this group, possibly none has been productive of so much harm as that of closure of the cervix for the cure of lacerations. In the majority of cases it is an unnecessary operation, and if imperfectly or carelessly done, on properly selected cases even, the ultimate outcome often proves an added mischief. The history of a case recently operated on by the writer for the removal of diseased appendages, the result, no doubt, of an Emmett operation on the cervix thirteen months previously, may be of interest in this connection.

The patient, aged thirty years, the wife of a banker, had always been healthy to the time of her first accouchement, six years ago. She is the mother of four children, the eldest six years of age. All her labors were of short duration, with speedy recoveries. In her first confinement she sustained a laceration of the cervix and an incomplete tear of the perineum, and for several years after complained of a dragging sensation in the pelvis. In May, 1893, she had the cervix and perineum repaired by a prominent Philadelphia gynecologist, and after several weeks she returned to her home in an improved condition, which lasted for several months. At the end of this brief probatory period an offensive discharge appeared, and she began to suffer from pains in both inguinal and hypogastric regions, shooting down the thighs, violent dysmenorrhœa and headache. She placed herself under the care of a physician of local repute in the treatment of gynecological ailments in a neighboring town, and went the rounds of boroglyceride tampons and applications to the cervix, her condition growing worse daily.

I first saw the patient on May 7, 1894. She was greatly emaciated, weighing only eighty-seven pounds. Her drawn features and anxious expression gave evidence of intense suffering. She had a retarded gait, her appetite was poor, bowels constipated. She suffered from alternating chills and flushes of heat, and complained of pains involving almost every portion of her body, her suffering being especially aggravated in the lower abdomen and pelvis. She could not stand, lie or sit with comfort.

On examination I found both ovaries enlarged to the size of small oranges, tubes tortuous, distended and very tender. Uterus in a state of metritis; cervix eroded and the site of a muco-purulent discharge.

With a view to better her condition she was placed on

Strychnia sulphatis.....	gr. 1-60

Three times daily and hot vaginal douches.

This treatment being continued for a month and her condition becoming more alarming, radical operation was decided upon. This was performed June 9, 1894. The patient received the usual preliminary treatment of baths, douches and purge the day before the operation. The next morning, assisted by Dr. J. M. Fisher and my father, Dr. T. J. B. Rhoads, the vagina was thoroughly scrubbed and douched and the uterus dilated and curetted to remove all the diseased endometrium, a strip of iodoform gauze being carried to the fundus for drainage. She was then placed in Trendelenburg's posture and an incision four inches long made through the linea alba. The intestines were found to be adherent to the uterus and ovaries and the adhesions were broken up. The elongated and distended tubes were inflamed and adherent, with the fimbriated extremities sealed, the ovaries enlarged and cystic, and attached to the left ovary was a small pedunculated fibroid. The appendages were raised through the abdominal incision, tied off with silk ligatures and removed. There was some oozing from the right stump, the ligature having cut through the friable diseased tissue, so a second transfixion ligature was applied which left a dry stump. I might say here incidentally, for inspecting the pelvic organs in these cases I use an abdominal retractor which I devised some time ago, and find it of great aid. It consists of a light U-shaped steel frame, on the upright arms of which slides a cross-bar with spring ends working in a ratchet. On this sliding cross-bar and the base of the U are movable retractors which, when the instrument is placed in position, hold it firmly and retract the wound to any desired extent. The instrument can be applied and removed in a few seconds, and takes the place of an assistant where light and room are necessary factors.

All oozing then being controlled the peritoneum was sponged dry, the omentum brought down to as near a physiological position as possible, and the abdomen was closed with a single row of silkworm-gut sutures, without previous douching or drainage. The wound was covered with an aristol-collodion gauze dressing consisting of a small aseptic gauze pad overlapping the stitch holes so that the collodion which sealed its edges would not come in direct contact with the line of suture. The patient was kept on her back twenty-four hours, then turned carefully on her side. Stitches were removed on the tenth day, the wound having healed nicely, and at the end of the fourth week the patient walked about her apartments. She has improved in health and spirits, takes long daily walks and is daily gaining in weight.

In this case, then, we have an instance where radical interference was necessary to undo the mischief done by a closure of the cervix. An effort had been made to relieve the patient of a minor ailment by this means, and a major operation was necessary to undo the evil wrought.

Closure of the cervix is an operation that is indicated in only a limited number of cases. A cervix laceration may generally be considered physiological (Parvin, "Science and Art of Obstetrics," p. 62, 1890), an exaggerated anterior and posterior lip, and will not often need attention. If serious hemorrhage results from the recent lesion a few stitches may be placed with advantage, but these cases are not so frequent as might at first sight appear. It is remarkable how quickly a tear of the cervix heals, providing the parts are kept clean. The scar tissue contracts so as to minimize the lesion, and the uterus accommodates itself to its new condition, no inconvenience resulting to the patient, even though the tear may have extended up the vaginal vault on either side. The scar thus formed is the normal result of nature's efforts to heal a raw surface, and there cannot follow from it *per se* the ill effects that have at various times been claimed. Where a condition of pelvic distress has arisen months after a protracted and complicated labor in which the cervix was ruptured, the cicatrix has been regarded to be the cause of the trouble, and unsuccessful attempts to cure the symptoms have been made by carefully dissecting out the cicatrix and uniting the denuded surface. The investigations of Boise (*Physician and Surgeon*, September, 1893), however, clearly show that a laceration uncomplicated by a pathological condition other than cicatricial tissue will not cause local symptoms, and other conditions must exist, possibly metritis or

displacement. Successful treatment must be directed against these abnormalities.

The cases of laceration of the cervix with erosion and eversion that are treated by denuding and closing the cervix fail in the majority of cases to cure the existing symptoms for the reason that primarily the laceration, secondarily the eversion and erosion, are considered to be the cause of the local symptoms and reflex disturbances, when in reality they are only the effects of a pathological condition further up the canal. When the condition within the canal is cured, the erosion at the neck and mouth of the canal will generally disappear under warm-water injections. Very likely the cases of eversion and erosion which are reported cured by the Emmett operation were those in which there existed at the same time marked subinvolution of the uterus. These cases can be benefited by the operation, and are practically the only ones where decided good can result.

There is a class of patients that present themselves with vague pelvic and general pains and a lacerated cervix, and operation is done, as it frequently is, merely for its cosmetic effect. These cases will not only experience no relief from their symptoms, but will be subject to the liability to various septic processes and, as is often the case, disastrous results. It may mark the onset of serious pelvic trouble, the injury resulting being due to one of three conditions or all combined.

1. Imperfect antisepsis; bacteria being carried directly to the denuded surface from instruments not made sterile or the hands and operation site not thoroughly cleansed.

2. A cervix operation is a surgical traumatism, and conditions therefore exist with a possibility for inflammation, toxemia and septicemia.

3. Mechanical obstruction. This point is clearly described by Montgomery ("Proceedings Philadelphia County Medical Society," vol. xi): "As a result of subinvolution of the mucous membrane we have an increased amount of secretion which, after narrowing of the cervical canal by the operation, is unable to escape freely. Consequently the uterus becomes dilated to a certain extent, and this favors more rapid extension into the Fallopian tubes and the development of serious trouble." The presence of germs in this state will quickly light up an inflammation, and previously healthy structures are transformed into a condition which, beginning with a cervicitis, has as its sequel pelvic abscess.

I had under my care several months ago from a near city a woman whose cervix was torn in labor two years previously. One-half year later Emmett's operation was performed and was followed by aggravated dysmenorrhœa. On examination I found a very small os. An endometritis had developed—the beginning of a process which might have eventuated in the conditions just named. The disease, however, was still limited to the uterus. She was etherized, and an attempt made to pass the smallest size Pratt's dilator failed. The cervix was then incised on each side, the canal dilated and curetted, with a drain of iodoform gauze. She made a satisfactory recovery and just missed the more serious consequences from the closure of the cervix.

When disease of the appendages already exists, operations on the cervix have a still more serious significance. It is very evident how the pelvic organs can be transformed into a violent inflammatory mass from a traumatism to the uterus under these conditions. Pus and peritonitis are the common results. Pepper ("System of Medicine," vol. iv) refers to the dangers of operation under these circumstances, and gynecologists are constantly called upon to do operations attended with no small amount of risk, in order to save the lives of patients suffering from advanced pelvic disease aggravated by cervical operations. Price ("Proceedings Philadelphia County Medical Society," vol. xi) in an earnest paper counsels more conservatism in dealing with the cervix, and Emmett ("Surgery of the Cervix," 1869) himself, the originator of the operation, finds occasion to say in reference to the subject that his ingenuity is oftener taxed to repair the damages inflicted by means used to afford relief than from the result of disease uncomplicated.

I desire, then, to present the following points for discussion by the society:

1. Laceration of the cervix is rarely productive of serious symptoms and seldom requires operation.

2. Emmett's operation if done on improperly selected cases is not alone barren of good results, but often aggravates existing diseased conditions and not infrequently is the exciting cause of pathological processes in previously healthy structures.

SENILE ENLARGEMENT OF THE PROSTATE—NOTES OF A CASE IN PRACTICE.

JOHN W. S. McCULLOUGH, M.D., ALLISTON, ONT.

On the 29th of September, 1890, I was called to meet two medical men in consultation on a gentleman, a farmer in easy circumstances aged sixty-one years. He gave the following history: During a month or two he had been troubled with undue frequency in passing urine, especially at night, having to rise three or four times from his bed for that purpose. Two days previous to my visit he had been engaged in threshing, had caught cold, and on getting up at midnight of the 27th was unable to pass his urine, which was causing him considerable uneasiness. A medical man was sent for, but not being able to come at once sent some opium powders, and next morning finding his patient unimproved tried to pass a catheter but failed. The patient succeeded during the day in passing a few drams of urine, but not improving any, another medical man was called. Catheterization was again tried, but failed to attain the desired result. The next day on my arrival I found the patient in severe pain, with the bladder distended and with a temperature of 102° F., pulse feeble and beating 120. The medical attendants told me they had made several endeavors to pass a catheter, but failed, and in fact were ordered to desist by the patient on account of the pain and distress they caused him. Their efforts were, I do not doubt, persistent enough, for the urethral canal was discharging blood. They had made a diagnosis of stricture.

I found (per rectum) the prostate much enlarged, and in consultation dissented from the diagnosis made. Neither of the doctors would agree, nor would the patient, with my opinion that the bladder was engorged with urine. They were doubtless deceived by the fact that the patient was passing a small quantity of urine frequently, as evidenced by the angry words of the patient: "Don't tell me my bladder is full when I'm passing water every few minutes." I explained that this was due to an overflow and that pain and distress were due to distention, but it was with very great difficulty that I succeeded in inducing him to allow me try to pass a catheter, and only after promising to desist if I hurt him. I tried a No. 7 English and then a No. 3 English. I failed with both.

I had with me several catheters overcurved on stylets in the manner advised by Sir Henry Thompson, of the University College Hospital, London, and I determined to give them a faithful trial. First I gave the patient ¼ gr. morphia sulph. hypodermically; then put him in a sitz-bath at 105° F. for 35 minutes. I then tried to pass one of my over-curved catheters (without stylet, of course) and succeeded without any difficulty in getting it into the bladder. By this means I was enabled to withdraw (which I did gradually) about forty ounces of very inodorous urine, much to my own and the patient's satisfaction. I washed out the bladder with a weak solution of acid. boric. and left directions for the urine to be withdrawn every three hours. The patient was given a dose of cascara and ordered

Syr. zingib..... q. s.
Every four hours.

Next morning I was called again. The urine had been allowed to accumulate for longer than three hours and defied the efforts of the attendant to pass the catheter. I had recourse to the hot bath again and soon overcame the difficulty.

Three days later there was the same trouble, but on this occasion I was able to pass a French coudée without assistance of the bath. Then I instructed patient in the use of the instrument and left him a supply, one of which he occasionally uses. He has had the best of health during the last four years and bids fair to live to a ripe old age.

THE corset has figures to show—
Despite what the doctors may say—
That while fashions may come and may go,
It is certainly with us to "stay."

A PRACTICAL STUDY OF SERIOUS ABDOMINAL CONTUSIONS, WITH A CLINICAL REPORT OF TWENTY-ONE CASES.*

THOMAS H. MANLY, M.D., NEW YORK.

[CONTINUED FROM PAGE 862.]

REPORT OF CASES.

CASE I.—Contusion of abdomen and fractured ribs in a pregnant female. History: Annie N., aged 40; married; admitted to hospital June 25, 1891, by ambulance.

Patient was hanging out clothes, holding the line while she leaned over the window-sill on the fourth story, when the line broke and she fell, striking on the stone flags below. On examination, fracture of the ninth, tenth and eleventh ribs was discovered and the right lumbar region was severely contused. She was at this time eight months pregnant. On admission, in great shock, she complained of intense pain over the right kidney. The whole abdomen was exquisitely sensitive. Placental and fœtal heart sounds distinct on auscultation. Unable to urinate; some nausea.

Withdrew six ounces of urine, which was densely saturated with blood. There was a large bulging tumefaction just anterior to the right kidney which was suggestive of extravasation of blood or urine. As soon as she entered the hospital restoratives were administered and a firm binder applied.

Great prostration; no paralysis and no cerebral complication.

On second day after admission she had fairly reacted. Temperature, 101.5° F.; pulse, 110; respirations rather shallow.

Remained about the same, passing large quantities of blood with the urine. On the evening of the twenty-eighth day she was taken with severe labor pains. At 1 A.M., twenty-ninth, she was delivered with the aid of the forceps of a dead male child. Delivery easy and without accident.

Everything went well until the evening of the following day, the thirtieth, when collapse suddenly set in and she sank at 7.40. A post-mortem examination was denied.

This case derives its peculiar interest from the physiological condition of the patient at the time the traumatism was sustained. Although physical evidence proved that the infant was not killed outright, it finally succumbed from the great exsanguination which its mother endured through an extensive laceration of the kidney and secondary shock.

Experience teaches us that when labor sets in at advanced term after great bodily injury, the danger to life is great.

From a medico-legal standpoint an important question might arise here as to whether it could be proved that the death of the child could be traced to the injury when, as in this case, its body bore no evidence of trauma.

There was all the more reason for the question to arise in this case, as the house surgeon saw fit to expedite labor with the forceps. The renal lesion here was well pronounced, for there was evidently a through-and-through rent, inasmuch as blood flowed off in large quantities through the pelvis and out of the urethra. Besides, the extravasate into the retroperitoneal tissues was voluminous.

It was my opinion that renal exsanguination led directly to the death of mother and child.

CASE II.—Contusion by fall. History: Patient aged 20; bricklayer; married; admitted to hospital February 26, 1890, by ambulance. Diagnosis: Contusion of abdomen, fracture of right ilium and pubis.

Patient while walking on scaffolding made a misstep and fell four stories (about fifty feet), striking his abdomen and pelvis on the right side. Immediately sent to hospital. On admission, in great shock, deathly pale; limbs and body deeply cyanotic. Stimulants freely plied and heat applied to the extremities. As reaction set in violent projectile vomiting commenced, but no blood was ejected. As rupture of the bladder was suspected it was distended with ten ounces, but this returned without any blood tinge. The integuments over the hip were deeply ecchymotic and a linear fracture was discovered running vertically through the

*Read at the annual meeting of the New York State Medical Association, October 10, 1894.

ilium, between the anterior superior and inferior spines, besides another through the center of the horizontal ramus of the pubis on the right side. The right inguinal region was full and evidently distended by a large intraperitoneal effusion of blood. The pelvis was firmly fixed by a strong binder and steadied by sand-bags. Opium freely given for the first four days. Moderate tympanites with hyperæsthesia of surface. Had to be catheterized for one week. Bowels opened by a clyster on the fifth day.

Recovery rapid, and patient returned home March 29th, with instructions to continue use of strong binder for the next three months.

The case was one in which the body itself was the moving agent which, in its rebound as it came in contact with the earth, suffered damage over the hypogastrium and the pelvic bones. The skeleton evidently scattered the momentum of impact at the expense of its continuity.

There was no loss of blood beyond that into the iliac fossa nor serious injury of any internal organs.

Case III.—Compressive contusion. History: Miles J.; driver; married; aged thirty-nine years; admitted December 15, 1889, by ambulance. Diagnosis: Contusion of back and abdomen; traumatic peritonitis.

Patient was driving a cart loaded with brownstone in a stone-yard three days before admission, when he was thrown off forward and the wheel of one side passed over the abdomen.

No great pain was experienced at the time, but two days later it commenced and he was sent to the hospital.

When admitted he was placed in the medical ward, as it was supposed that he had simple traumatic peritonitis. His condition rapidly improved after he had been placed on treatment, and after the second day he was up about the ward, feeling much improved. On the 22d, however, seven days after admission, pain again set in with great severity; rise of temperature, great weakness and rapid distention of the abdomen, making respiration quicker, more labored and painful.

On physical examination of the abdomen it was evident that there was a large liquid accumulation, but what its precise character was it was impossible to determine by any special symptom.

To determine this an exploratory needle was passed in over the right flank. On its withdrawal it was evident that the material consisted of bile.

Now diagnosis of rupture of the gall-bladder was made, when the case was transferred from the medical to the surgical division for further treatment. At this time his general condition was very bad, and the extent of abdominal distention was so great as to render breathing extremely difficult.

An operation was now undertaken with a view of draining away the fluid and, if the patient's condition permitted, endeavor to close the rent in the gall-bladder. An oblique incision was made on the right of the median line along the slope of the floating ribs. Through this 732 ounces of bile escaped, or 5¼ gallons.

He almost at once went into mortal shock after the peritoneum was opened, dying on the evening of the 25th, eight hours after operation.

Autopsy.—The following day autopsy was made. General peritonitis, with deep bronzing of all the viscera.

A perforation about one line in length was found in the posterior wall of the common bile-duct. It was of a linear direction. In the immediate vicinity of the erosion there were evidences of previous adhesive inflammation having formed, which subsequently gave way, permitting a leakage into the cavity of the general peritoneum.

This was a case of compressive contusion and belonged to that consecutive type of rupture of the viscera which may succeed at various periods after the original injury is sustained. Here we note steady improvement for the first week under constitutional medication. Adhesive inflammation had begun to wall off the site of the contusion and of leakage in the choloduct. But he was imprudently permitted to leave his bed too soon, and in some sudden commotion of the body the adhesions were broken and the peritoneum became infected. From the side of diagnosis and treatment the case furnishes us with many important speculations and suggestions. It accentuated the well-known difficulties in diagnosis and prognosis so characteristic of traumatic intraperitoneal lesions, for in the beginning it was supposed to be so benign a case that recovery was almost a certainty. A laparotomy at an earlier

stage after admission of this case could have availed nothing; on the contrary, it no doubt would have been promptly followed by a fatal termination.

In this class of cases we should observe Hinton's dogma of rest of an injured organ, and in all cases of hepatic traumatisms we should endeavor, as far as possible, to diminish the physiological functions of the liver. This can be accomplished by permitting nothing to enter the stomach except small quantities of water, alimentation being maintained entirely by the rectum, until we are assured that reparative processes are complete.

CASE IV.—Contusion by a fall; death of fœtus; hemorrhage; peritonitis; laparotomy. History: Patient 28 years old; a female. Diagnosis: Acute traumatic peritonitis. Mrs. M., married six months. For five months prior to accident menstruation ceased. The breasts had become fuller and the abdomen enlarged. Besides, she had morning nausea and for some time had noticed swelling of her ankles.

On the afternoon of June 12, 1889, patient, while crossing on some planks over an excavation in the sidewalk, was injured severely over the abdomen by one of the planks rolling from under her feet. She came down with great force on the abdomen. Some workmen near by who saw her fall came to her assistance and lifted her out of the trench into which she had fallen.

She was in great pain, but would not have an ambulance called. After resting about an hour and having had some stimulants, she walked home—about a quarter of a mile. In the night she had severe abdominal pains and sent for a physician. He ordered sedatives, and the next day, though she could not leave her bed, she felt much relieved. But late in the night violent pain set in, and the abdomen became greatly distended. She became steadily worse until the fourth day, when she had a flow from the vagina which gave her some relief. The next day worse than ever, when the physician was changed. He was so alarmed at her condition that he immediately gave an unfavorable prognosis and recommended a consultation, when I was invited in.

I found a woman with all the symptoms of advanced acute peritonitis. On examination of the abdomen under chloroform, a large mass was made out to the left of the median line, rather above the iliac fossa. It had a hard, resistant feel, and was altogether too large for a pelvic abscess, besides being out of its radius. Over on the right side, anterior to the kidney, was another fullness, which, however, was very freely movable, and of such a puzzling outline and conformation that I could scarcely venture a guess of what it was. Having hurriedly run over in my mind the various lesions here seen after traumatism, and remembering that the woman gave a history of pregnancy, it occurred to me that possibly this was a case of extra-uterine pregnancy. In any event I advised that a section of the abdomen be made at the earliest moment. The next morning with assistance I opened the abdominal cavity. The large mass on the right side was found to be a vast effusion of coagulated blood, at the bottom of which was a placental growth imbedded in the broad ligament. From this a cord extended across the peritoneum to the right side, under the kidney. Here a five months' fœtus was found lying in the free peritoneal cavity. The placenta was detached and the peritoneal cavity well irrigated. Recovery ensued, though convalescence was tedious.

The above case was one of a unique and extraordinary character. Her large vaginal hemorrhage on the second day after injury, together with the presence of a deciduous membrane, deceived the first medical attendant, as it indicated an abortion. Although at time of operation her condition was most unpropitious, yet with a temperature of 104° and a pulse of 138 she promptly rallied and made an excellent recovery.

In this woman's singular case, in which it is very probable that, though paradoxical as it may seem, an accident which endangered her life led to its preservation from a pathological condition certain to follow, there were no traces of discoloration of integument over the seat of injury.

CASE V.—Percussive contusion; rupture of ureter; moderate peritonitis. History: Patient male; married; forty-one years old. This case came under my care eight years ago, in the spring of 1886. Patient was a derrick-man. While swinging blasted rocks on to a wagon he accidentally got in the way of a large moving bowlder and was violently struck over the

right antero-lateral zone of the abdomen, immediately below and to the right of the umbilicus. He was knocked down and for nearly an hour was unable to rise. But after a while, when he had taken freely of hot whisky, he got up and went home unaided. The next day he was seen by me. Now, although the entire abdomen was sensitive, the most intense pain was in the right lumbar region. His urine, which was passed with great difficulty, was at first very bloody; constitutional disturbance was not marked and no great pain except on movement of the body. He was suffering from moderate traumatic peritonitis and a general bruising of the abdomen. After ten days in bed he made a good recovery, except for a swelling which appeared as soon as he took his feet. This was lodged in the right lumbar region. It was about the size of a small cocoanut, fluctuated and was moderately compressible. As there was now no rise of temperature it was evident that it was not an abscess. Its anterior integumental covering was deeply ecchymosed.

An exploratory needle was passed in, when it was found that the collection was urine. A large aspirating needle, with a vacuum attachment, was then sent in and eleven ounces of urine withdrawn. On the third day following it was again aspirated and nine ounces withdrawn. It but moderately filled again, and in a little while the tumor gradually commenced to diminish in volume and sensitiveness. In a little while longer it had wholly disappeared. In order to positively determine the nature of the aspirated fluid, a chemical analysis was made of it and it was proved to contain nothing but the elements of the normal urine. This case was remarkable as illustrating how the deeply lodged ureters may suffer severe contusion or laceration while the more superficial organs escape. It besides demonstrated how little constitutional disturbance attends the extravasate of healthy urine when it is uncontaminated and effectively encysted.

Case VI.—Compressive abdominal contusion. History: Patient a child nine years old; male; admitted to hospital August 16, 1884. Diagnosis: Abdominal contusion with internal hemorrhage.

Patient climbed on to a vender's heavily loaded coal wagon, when the horse suddenly started and he fell forward, both wheels passing over the abdomen. Those who saw the accident supposed that the boy was killed. He was unable to rise and groaned from pain in the abdomen.

When brought to the hospital he was in great pain and almost pulseless; extremities cool and of a deathly pallor; vomited blood-stained fluid and complained of much pain in the region of the bladder. About one ounce of limpid urine was drawn off, and on test of the bladder it was found that there was no rupture. Moderate doses of opium were given and local applications employed. Reaction slow. The following morning abdomen tympanitic and extremely sensitive; unable to retain anything in the stomach and thirst was intense.

On the fourth day after entrance temperature, which had run high, was nearly normal, the bowels opened, and he passed with stool a large quantity of blackened, partly digested blood. From this time improvement was steady and he left the hospital in good form September 20th.

Hemorrhage is always badly borne in growing children when its quantity is large. In this case the greatest immediate danger arose from this source.

There had evidently been a considerable loss both within the lumen of the bowel and into the peritoneal cavity.

It seemed almost inconceivable that a cart carrying more than a ton of coal could pass over this boy's body without doing great destruction to the viscera within. Yet he survived it, and at no time after injury was there any discoloration of the abdominal integument.

A sharp attack of peritonitis followed, but, as is usual with most cases of this malady in non-penetrating abdominal injuries, it underwent favorable resolution.

Case VII.—Contusion of the abdomen by percussion. History: Patient aged twenty-nine; married; female; housekeeper; admitted July 7, 1893. Diagnosis: Contusion of abdomen with fracture of the tenth and eleventh ribs on right side.

This woman was seriously injured, as a great many are every year in this city, by the breaking of a clothes-line while hanging out clothes through a window at a considerable elevation from the ground. When the line which she held broke she went out of the window and fell three stories to the ground, striking in transit on her abdomen across a fence.

When she entered hospital was in profound shock, though rational. Muscles of the abdomen tense and physical evidence of free hemorrhage into the peritoneal cavity.

Abdominal pain extreme and great distress over the liver on any motion of the body. Fracture of tenth and eleventh ribs, but no displacement nor crepitation.

Pulse extremely rapid and feeble. Morphine had to be given in large and frequent doses to alleviate abdominal pain. No blood in the urine, but there was a free discharge of it from the vagina.

She constantly complained of most agonizing distress over the umbilicus. Frequently vomiting a greenish watery fluid with no blood. Reaction had fairly set in the following day; she had all the symptoms of peritonitis. Examination *per vaginam* revealed a state of pelvic cellulitis.

Alimentation entirely by the rectum for the first five days. Abdominal meteorism great and respiration sighing and shallow. By the sixth day the temperature had reached 104.6°; pulse, 134; respiration, 38.

After this date improvement commenced and continued uninterruptedly until her recovery. She left the hospital September 26th.

In this case a fearless operator might have opened the abdomen for exploratory purposes, but with the shock she was in it would have been indeed a bold step, and even should she survive it it would have accomplished no good. It would have left a weak abdominal wall with a tendency to ventral hernia, a deplorable condition for a working, child-bearing woman.

Here there was presumably laceration of the liver, with every probability of a rupture of the intestine, which was evidently sealed by an agglutinative peritonitis. Her vaginal hemorrhage was of uterine origin, produced by direct injury to this organ.

The tympanites in this case was so great and prolonged that had it occurred in the male it would probably have ended mortally by paralysis of the diaphragm; but in the female, where respiration is chiefly costal, an enormous abdominal distention can be endured with impunity. Besides, there can be no question but that women bear peritonitis and its resulting pain with much greater prospects of recovery than do men.

Opium in large and frequent doses was our sheet anchor in this case.

CASE VIII.—Compressive contusion; the body supine. History: Patient, William H.; eighteen years of age; single; admitted to hospital April 23, 1891, by ambulance. Diagnosis: Contusion of abdomen; internal hemorrhage; traumatic peritonitis; rupture of bowel.

On the evening of April 23d patient, who was an epileptic, was seized with a fit on Third Avenue. In order to try and save himself from falling he rushed into the street and seized the front wheel of a heavily loaded express wagon; was drawn under and run over by it. He was immediately brought into hospital by the ambulance. On admission he was in great shock and constantly groaned with pain.

No external evidence of contusion was found. Complained of great pain in abdomen and desire to urinate, but could not. Catheter evacuated six ounces of very bloody urine. Pulse and respiration rapid and feeble. Vomiting set in soon after entrance; ejecta bilious but containing no blood.

Treatment.—Hot applications and stimulants, with enough narcotics to subdue pain. Temperature, 97.2°; pulse, 110; respiration, 26.

April 24th. 6 A.M., temperature, 97.6°; pulse, 102; respiration, 24. 6 P.M., temperature, 97.4°; pulse, 100; respiration, 22.

April 25th. 6 A.M., temperature, 100.6°; pulse, 116; respiration, 22. 6 P.M., temperature, 99.5°; pulse, 120; respiration, 22. Pulse weak and thready; tympanites well marked; fed freely per enemata with egg-nog and milk-punch. The slightest bodily movement or coughing aggravated his distress; urine still bloody, but less so than on the first day.

April 26th. Temperature, 99.8°; pulse, 120; respiration, 28.

April 27th. Temperature, 101.6°; pulse, 110; respiration, 28.

April 28th. Temperature, 104.4°; pulse, 120; respiration, 22.

April 29th. Temperature, 101.3°; pulse, 120; respiration, 24.

April 30th. Temperature, 102.4°; pulse, 104; respiration, 24.

May 1st. Temperature, 99°; pulse, 112; respiration, 24.

May 2d. Temperature, 104°; pulse, 120; respiration, 25. On this date patient was freely sponged with alcohol, and afterward temperature fell to 101.2°. General peritonitis now well developed.

May 3d. Temperature, 102°; pulse, 100; respiration, 26. Patient now begins to show signs of lobar pneumonia. A large hot jacket poultice now applied, which extended from the pubes to clavicle, and frequently renewed.

May 4th. Temperature, 102.6°; pulse, 100; respiration, 26.

May 5th. Temperature, 102°; pulse, 130; respiration, 40. Now stimulated and nourished by the mouth.

May 6th. Temperature, 102.6°; pulse, 112; respiration, 32. Patient's general condition was very much improved. Bowels spontaneously opened to-day for the first time; breathing much easier and sleep returning.

Was steadily improving, and on May 13th temperature, 98.6°; pulse, 109; respiration, 27.

May 11th. Patient had an epileptic convulsion.

May 14th. Temperature, 101½°; pulse, 110; respiration, 20.

May 20th. Temperature, 100.6°; pulse, 120; poultices discontinued.

May 21st. Temperature, 104°; pulse, 110; respiration, 24.

May 22d. Temperature, 100°; pulse, 90; respiration, 19.

May 24th. Pulse and respiration normal. Patient rapidly convalescing.

May 30th. Patient discharged cured.

The above case was one attended with several serious complications. First, the injury to the renal tissues; second, internal hemorrhage; third, probable rupture of the intestine; fourth, general peritonitis, besides lobar pneumonia, presumably from injury to the lung.

In this case, as with the previous two, the viscera were crushed against the vertebral column. The extent of shock was considerable, and yet, with all the proof we had of serious internal injury of the abdomen and thoracic viscera, there was nothing to indicate it on the abdominal walls. Recovery under these circumstances emphasizes what nature will accomplish in this class of cases without resort to heroic surgical intervention, and that traumatic peritonitis, even of a very aggravated type, if appropriately treated, may do well without incision or drainage.

CASE IX.—Direct contusion and compression; peritonitis; rupture of thoracic duct. History: Patient thirty-five years old; married; male; admitted to hospital July 3, 1893. Patient when alighting from a street-car was violently struck by the pole of a brewery wagon, was knocked down and run over by the hind wheel. An ambulance was called and patient was sent to hospital. Patient in much shock. There was an abrasion over the right iliac crest anteriorly. Complained of great pain in the lower abdomen; unable to urinate, though he had a constant desire to; urine withdrawn and bladder tested for rupture.

On third day temperature had reached 100°, pulse 86 and respiration 32; pain not so severe; appetite much improved, but is steadily losing strength.

On July 10th a large mass was detected in the right flank, which fluctuated on palpation; flat on percussion. It evidently was lodged behind the peritoneum and displaced the intestine forward and inward.

It was at first supposed to be a hæmatoma, but on penetration with hypodermic needle was found to be pure chyle

On July 15th a free incision was made into the tumor and a little more than seventeen ounces evacuated of a thin milky fluid. It was of sweetish odor, slightly saline taste and resembling very much human milk. On chemical and microscopical analysis it was found to be chyle.

For the first three days about eight ounces a day escaped through the puncture and was secured.

On the 18th and 19th about two ounces escaped each day. From this time the quantity gradually diminished until the 21st, when it quite ceased. Specific gravity of fluid varied in different days and various hours of the same day, always flowing more plentifully after taking nourishment; general strength improved after lactocele dried up; had painful vesical trouble for some time after, though by October 21st he had recovered sufficiently to return to his home.

This case was highly interesting from various considerations. The injury was produced by a compound force, first the blow of the carriage-pole, and, secondly, the weight of the passing loaded beer-wagon. There are reasons to believe

that the former struck the hypogastrium with great force, doing damage to the thoracic duct by crushing it against the body of the second lumbar vertebra, on which it rests; and, secondly, that all the viscera, especially the bladder, suffered by the compressing force of the vehicle.

Traumatic lesions of the thoracic duct from concussive violence are exceedingly rare. In this instance its rupture evidently was secondary to contusion. The escaping fluid made its way through the retroperitoneal tissues, finally gravitating into the iliac fossa. By rest in bed the rent apparently closed of itself, when the salutary effects on nutritive processes were distinctly marked.

CASE X.—Compressive contusion; shock; hemorrhage and rupture of intestine. History: P. K., aged 34; married; male; admitted to hospital June 24, 1893. Diagnosis: Contusion of abdomen with internal hemorrhage.

Patient was a middle-sized man, a driver of a cart in the Department of Street Cleaning. On the morning of above date, as he was hurriedly urging his horse up the "run" to dump his load of street garbage in a scow below, a rival driver collided with his cart, throwing him off, when the wheel of one side rolled over his body as he lay on his back. He was unable to rise unaided.

An ambulance was summoned. When he entered the hospital he was in great collapse; some vomiting of blood with great pain over the umbilicus. Warm applications to cold extremities; internal stimulation and narcotics. Pulse extremely small and rapid; temperature subnormal.

From the extreme pallor it was supposed that he had a large internal hemorrhage, yet there were wanting the physical signs of it.

June 25th. Seemed somewhat better in the morning, but toward noon pain set in again with greater severity than ever, with incessant vomiting; abdomen now ballooned up and exquisitely sensitive; collapse deepening; moribund state approaching. Died on this day at 2.40 P.M.

Autopsy. — Twenty-four hours after death the body was examined. Now there were two well marked ecchymotic spots visible, one over the anterior superior spine ilium on right side, and one further down over a space in about the middle of Poupart's ligament. On opening the serous cavity a large effusion of blood was discovered between the omental apron and Cooper's fascia.

On dividing the omentum it was seen that there had been a rupture through the jejunum in about its center. The opening was about three centimeters in length and looked as though it had been produced by a direct laceration. Particles of digestive aliment were found mixed with a large serous effusion. No evidence of serious damage to the other adjacent organs. This was a case which, had its precise character been understood, might have been treated by laparotomy with reasonable success.

It is true that he was in great shock for some hours after admission, and the free hæmatemesis which he had on admission greatly exsanguinated him, yet probably we could scarcely hope for a more desirable case to test it on than this was.

I must confess that when I saw him the morning after injury there were no desperate symptoms present, and it seemed to me that the case was by no means without hope. But one of the house staff ventured to suggest that there might be intestinal rupture. It was then suggested to the patient that a laparotomy might become imperative if worse symptoms should set in. This, however, he would not permit under any circumstances.

The mortal termination was as sudden as it was unexpected, but it was entirely in keeping with the alarming rapidity of serious changes so often witnessed after peritoneal traumatisms.

CASE XI.—Direct contusion of abdomen; peritonitis and rupture of jejunum. History: Patient aged twenty-three; single; male; admitted to hospital June 23, 1893. Diagnosis (primary): Severe contusion of abdomen. Patient was an operator on what is known as a circular ripsaw in a lumber yard. While feeding the saw, as he pressed a piece of lumber which had a knot in it, it splintered as the blade of the saw struck it, when a large piece rebounded and hit him a blow, as he said, on the pit of the stomach. He was felled by the blow, and remained unconscious some minutes before he was able to breathe.

Now the abdominal pain was very great and he was unable to rise. An ambulance

was called and he was brought into the hospital. Was in great shock on entrance.

June 24th. Vomited nearly everything he swallowed; considerable thirst, tympanitic abdomen and apparent peritonitis. Morphine freely administered hypodermically. Bowels constipated.

June 25th. Is growing steadily weaker and fails to respond to stimulants. Vomiting returned in an uncontrollable form. Collapse set in early in the evening and he died at midnight.

Autopsy.—The next afternoon the abdomen was opened. The peritoneal cavity was filled with blood and fluid of a fæcal character. General peritonitis. In about the center of the jejunum a rupture was discovered which extended about halfway through the intestinal coil; a dark, worm-eaten margin marked the site of perforation. The intestinal lumen for some distance beyond the point of injury was distended with blood, coagulated.

This case was a typical one of injury by percussive or contusive violence. The man was first hit with great force over a limited area, crowding the intestine against the spinal column and probably severely contusing the intestinal walls, probably splitting the internal tunics so seriously as to devitalize the part and favor speedy gangrene. In this case not the least visible trace of external violence could be seen and no rupture of muscle followed.

The first phase of serious abdominal injury was great shock, probably from contusion of the solar plexus and the heart, by concussion being transmitted through the diaphragm. Secondly, as reaction set in, hemorrhage into the intestine through laceration of its inner coats, and hemorrhage into the cavity of the peritoneum through injury to the vessels in the mesentery.

The last and fatal phase was consecutive gangrene of the bowel's wall, fæcal escape and fulminant peritonitis.

Case XII.—Contusion of abdomen by crushing. History: Patient forty-six years old; married; male; admitted to hospital June 17, 1894. Diagnosis: Contusion of abdomen, fracture of pelvis and internal hemorrhage.

This man was injured by being knocked down in the street by horses and then crushed under the hind wheel of a brewer's wagon which at the time was loaded with barrels of beer. The wheel in some unexplained manner came between the legs, passing up over the horizontal ramus of the pubes, the iliac fossa and the right lumbar region, the edge grazing the border of the integument over the floating ribs. He was immediately raised and transported to hospital; on admission in mortal collapse, the pulse barely countable and fast failing at the wrist.

He was perfectly rational and said he had no pain, but he knew his end was near and called for a priest.

On a superficial examination it was found that there was an extensive fracture through the pubic ramus and the iliac plate; the pelvis was filled with blood, which in the flanks produced large fluctuating projections; the bladder was empty and there were no signs of rupture; stimulation was not responded to and he rapidly sank two hours after admission.

In all cases of serious crushes of the lower abdomen complicated with fracture of the pelvic bones the resulting lesions are generally mortal. This is because the great blood-trunks or hollow viscera are either torn open by the sharp spiculæ or edges of fracture, or else lacerated, by the crushing force brought on them, against the sharp borders of the pelvic brim or some part of the linea-ileo-pectineal line. The man's death was plainly caused by shock and internal hemorrhage.

An autopsy was denied.

Case XIII.—Contusion of abdomen (percussive). History: Patient aged 42; single; male; admitted May 8, 1894. Diagnosis: Abdominal contusion with rupture of the spleen and internal hemorrhage.

Patient was a sailor who on the morning of entrance to hospital fell into the hold of the ship, striking on his left side over the sharp edge of a cask. He was lifted up in great collapse and sent to the hospital. Six hours after injury he was seen by me. At this time the abdomen was distended by a fluid accumulation and was extremely sensitive over the spleen, where he complained of most intense pain. There was no abrasion or discoloration of the integument over the abdomen. The pulse was exceedingly feeble. He was deathly pale, though the extremities were warm.

As this case seemed one in which a laparotomy might be borne with compara-

tive safety and there were unmistakable evidences of hemorrhage, after consultation with my colleague, Dr. Chas. B. White, and with his acquiescence, it was undertaken.

The patient took ether badly and struggled as he went under anæsthesia. His pulse seemed rather firmer when anæsthesia was complete.

Operation.—An incision was made to the left of the rectus muscle in an oblique direction outward and downward about four inches long. On puncturing the peritoneum, bright red blood spurted through.

Now hastily extending the incision and passing in the index and middle fingers, the spleen was reached. It was found badly lacerated, one fissure extending vertically upward, nearly cutting it in two. The organ was now carefully drawn into the incision, when its hilum was seized and the artery and vein being ligated separately with strong silk, the spleen was cut away. The peritoneal cavity was filled with blood. Before this could be removed by sponging mortal symptoms suddenly set in, breathing became irregular and shallow and he became pulseless. Time was barely permitted to close the incision with suture when he was dead.

The appalling suddenness of death here was startling in one who but a few moments before was in possession of all his faculties. Every possible care had been taken to provide against shock. The operating-room had been well heated, there was no peripheral loss of blood, and the time in operating occupied but a few minutes, as I was ably assisted by Dr. White and the house staff of four physicians. But the torrent of blood that came through when the peritoneum was opened, the sudden displacement of the large escape of it by the sponge and exposure of the peritoneum were too much for him.

Perhaps a laparotomy under these circumstances might seem a questionable procedure, yet it was in accordance with sound principles in surgery, for it seemed the only course open to the permanent and definite arrest of hemorrhage. My regrets in this case were that I touched him with a scalpel or forced my unfortunate patient into an ether coma, for it is my conviction that his chances of recovery were quite within the range of possibility if he had been allowed simple rest with an abundance of refrigerant drinks and stimulants. Nature's ways of arresting hemorrhage in the young and healthy are marvelous. Within the peritoneum the more blood escapes the greater is the pressure over the site of bleeding, mutilated tissue. The blood irritates the endothelial layer of the peritoneum and thereby provokes the abdominal muscles into rigid contraction, and hence we have an augmentation of intra-abdominal pressure. But by opening the abdomen nature's best efforts were thwarted and the only means by which life might have been spared may be rudely frustrated.

[TO BE CONTINUED.]

Etiology of Rheumatism.

One of the most commonly observed symptoms of a tired-out sympathetic system is disturbance of the digestive function, which is presided over by that system of nerves. The most common form of indigestion under these circumstances is the fermentative or acid. Hence the process is simple, the ingested food enters the stomach, where, owing to abnormal conditions, instead of exciting a physiological congestion of that organ and a properly increased flow of gastric juice, owing to the impaired condition of the sympathetic nerves, this does not occur, and as a consequence the food, instead of being digested, ferments, generating gas and lactic acid, the gas to be expelled and the acid to be absorbed with whatever peptones may result from the attempt at digestion, and the circulating fluid, the tissues and excretions of the body become vitiated by it, *i. e.*, the blood becomes less alkaline and the secretions less alkaline, or acid, producing the state of body most favorable for the accumulation of uric acid in its tissues. In this manner the way is paved from irritation of sympathetic nerve terminals to an excess of uric acid in the system, which constitutes with its attendant and resulting symptoms lithemia, and composes the necessary congeries of conditions the next step in advance of which, the proper exciting causes being added, is acute articular rheumatism.

A GREAT SPECULATION.—The price of Koch's new lymph is one dollar a dose. Further comment is unnecessary.

COMMUNICATIONS.

REMOVAL OF BOTH TESTICLES FOR CHRONIC HYPERTROPHY OF PROSTATE.*

J. D. THOMAS, M.D., PITTSBURG, PA.

I report the following case of double castration for enlarged prostate and chronic cystitis.

C. C., aged sixty years; German; by occupation a nurse; was sent into the South Side Hospital by Dr. J. E. T. Martin, under whose care he had been, on August 4, 1894, for operation. This was done on the following day. Patient has never had a venereal disease; he has a double hernia. About ten years ago he began to notice that he was urinating oftener than usual, and that he was obliged to get up during the night. This trouble grew worse year after year, until at present he is obliged to urinate every half-hour during the day and eight or ten times during the night. When he is urinating he is obliged to get upon his knees and succeeds in emptying his bladder by drops. This straining causes prolapsus of the rectum. The pain is so intense that the whole household is disturbed by his groans. Has been taking paregoric, on his own responsibility, to relieve this pain. In the past has resorted to the catheter, as his occupation made him familiar with its use; but the pain eventually became so intense with its use that he abandoned it. On examination of the urine it was found to be neutral and contained a large amount of pus; the patient described it as looking like thick buttermilk. Residual urine two ounces. The soft catheter passed without much difficulty, suggesting thereby that there was very little, if any, median hypertrophy. Examination by the rectum revealed both lobes of the prostate markedly but uniformly enlarged.

The choice of operation was left with the patient. As his virile powers had been lost for several years he chose double castration, which, with the assistance of Drs. O'Conner, Martin and others, I did as stated above. The patient remained in the hospital for five weeks, and during this time his bladder was thoroughly treated by Dr. Martin. Before the operation and for some weeks after his physical condition was very bad, but a perceptible improvement in the urinating function was noticeable in a few days, and this improvement has continued right along to the present, although he has had no medical treatment now for some weeks. He can at present retain his urine during the day for from two to six hours and during the night for two hours. Urination now causes very little pain; the urine is voided promptly and in a good stream. The urine still contains at times some flakes, but the patient states that there are other times when it is quite clear. By rectal examination a diminution in the size of the prostatic hypertrophy is patent to the finger. My impression is that his greatest discomfort at present comes from his double hernia. The patient and his family feel grateful for the marked improvement that has taken place since the operation.

I report this case as the operation resorted to is a comparatively new one for the cure of chronic hypertrophy of the prostate body. In this country I believe that Dr. J. William White, of Philadelphia, is the most ardent exponent of this operation. His experiments, as well as those of others, have demonstrated that in the dog the removal of the testicles is followed by atrophy of the prostate. Raum (*Therapeutic Gazette*) reports two cases "in which cystitis persisted, and which disappeared like magic after the removal of the testicles. The hypertrophy of the prostate decreased immediately." In my case the cystitis did not disappear "like magic," neither did the hypertrophy decrease "immediately," but the improve-

*Read before the Allegheny County Medical Society November 20, 1894.

ment took place gradually, continuously and satisfactorily.

During the month of August last I removed both testicles for tubercular disease. I reported this case in full to the society in August and again referred to it in September, although sufficient time had not elapsed to make an absolute prognosis. I sent for this patient last night and examined his prostate. It is much diminished in size, and the results are all that could be desired. In an editorial in the *Journal of the American Medical Association* this matter was recently taken up and a number of cases mentioned in California, in Philadelphia and elsewhere; but the report of this society was not recognized. Evidently the editor of the *Journal of the American Medical Association* does not read many medical journals.

NEPHRECTOMY FOR SARCOMA OF THE KIDNEY IN A CHILD TWENTY-FIVE MONTHS OLD.*

X. O. WERDER, M.D., PITTSBURG, PA.

Freda D., aged twenty-five months, has always been a healthy baby and is of healthy parentage. About three months ago Dr. E. S. Riggs, having been consulted about a small umbilical hernia, detected a growth in the left hypochondriac region somewhat larger than an egg. Since then it has been growing rapidly to its present size. The child has not seemed to suffer from the pressure of this growth, though lately she has been more irritable. Appetite has always been good, bowels regular, no symptoms of any disturbance of the urinary organs. Absence of hæmaturia. The child is plump and of healthy appearance, though her mother thinks that there has been some slight emaciation noticeable recently.

Physical examination reveals a large, somewhat elastic tumor occupying the left abdominial cavity, extending from the ribs to the crest of the ilium, and downward into the left iliac fossa, to within about an inch of the umbilicus and filling out the left lumbar region. The tumor is not sensitive to touch and is slightly movable in an antero-posterior direction.

Diagnosis of malignant tumor of the left kidney was made and nephrectomy proposed. Though a guarded prognosis was given as to the result of the operation and the possible return of the disease both by myself and the attending physician, Dr. Riggs, the parents consented to have an operation, which was performed August 29, 1894, at the Mercy Hospital.

Incision in the left linea semilunaris about six inches in length, which subsequently had to be enlarged to about eight inches, being very careful to avoid all hemorrhage. The tumor having been exposed, the peritoneum over it was incised, the very thin, fatty capsule surrounding it opened and rapidly peeled off, and the tumor lifted from its bed along with the kidney, which was behind and continuous with it. Pedicle ligated at the hilum of the kidney, including all its structures; several bleeding points ligated; cavity carefully sponged out and closed without sutures, and the abdominal wound united with silkworm-gut sutures without drainage.

The child stood the operation, which lasted from forty to forty-five minutes, remarkably well; during the whole operation certainly less than an ounce of blood was lost, as very careful hæmostasis was observed. There was no vomiting following the operation; pulse, after operation, 124; temperature next day up to 102°; but after that it varied from normal to 100°. Urinated spontaneously about two hours after the operation, and passed about ten ounces first night. Exact amount could not be estimated, as it was usually voided in bed. The child was discharged from the hospital well on the fifteenth day.

Pathological condition: Tumor irregular in shape; nodular growths at either end; attached to the anterior surface of the kidney, directly continuous with its structure, but only involving about one-third of the organ. Section showed interior growth to be soft, containing brain-like substance, in one portion beginning to

* Read before the Allegheny County Medical Society, November 20, 1894.

break down. Weight of tumor 2½ pounds; kidney not involved by growth, normal.

A microscopical examination, made by my assistant, Dr. F. Gibson, showed the growth to be a rhabdo-myosarcoma.

The case is interesting, especially for the reason that it demonstrates how well the youngest child will bear the most serious operations.

I saw the child a few weeks ago, when it was a picture of health, having gained considerable flesh since the operation.

TRANSLATIONS.

THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

TREATMENT OF MENINGITIS.

Dr. Melbec (*Revista Clinica e Terapeutica*, No. 10, 1894) in the treatment of acute meningitis advises avoidance of all excitement and emotions and rest in a well-ventilated and darkened room. Shave the patient's head and apply continuously an ice-bag. Each morning and evening administer a powder of the following formula:

Muriate quinine.....	0	30	grs. ivss
Benzo-naphthol.....	0	50	grs. viij

Sufficient for ten powders.

In case the restlessness be very intense order a soupspoonful of the following:

Bromide strontium.....	2	0	grs. xxx
Chloral.....	4	0	ʒj
Sirup opium.....	20	0	ʒv
Sirup hyoscyamus.....	40	0	ʒj ʒij
Wintergreen water.....	60	0	ʒij

Every two days give in the morning a powder containing

Calomel.....	0	50	grs. vijss

Let the diet consist of milk and broths.

Twice a day give a teaspoonful of the following:

Ext. cinchona..... }	āā 5	0	ʒj¼
Ext. kola..... }			
Sirup orange peel.....	150	0	ʒivss

In the tuberculous form one may frequently prevent the disease by forbidding the mother to nurse her child or that it be nursed by a tuberculous wet-nurse. Raise such children in the country and at the same time give them a teaspoonful of cod-liver oil daily. Each morning rub their bodies with cold water to which a little alcohol has been added. Develop the body by appropriate physical exercise and do not allow such children to commence their studies too early. Every day inject hypodermically, according to the age of the patient, one to two ccms. (gtts. xv–xxx) of the following:

Guaiacol..... }	āā 5	0	ʒj¼
Eucalyptol..... }			
Iodoform.....	1	0	grs xv
Sterilized olive oil.....	100	0	ʒiij ʒj

Every day administer in a little milk a powder of the following formula:

Calomel.....	1	0	grs. xv
Powdered sugar.....	2	0	grs. xxx

Sufficient for ten powders.

Counteract the restlessness, the cries and convulsions by ordering to be given every half-hour until quiet follows a teaspoonful of the following:

Bromide strontium.....	1	0	grs. xv
Chloral.....	0	50	grs. vijss
Sirup valerian.....	20	0	ʒv
Sirup peppermint.....	60	0	ʒij

An exclusive milk diet. The vomiting attacks may be prevented by increasing the dose of the bromide.

* In chage of the translator, F. H. Pritchard, M.D.

"MRS. BLINKS is quite ambitious to be considered a well-informed woman, isn't she?" Mrs. Banks—Yes, indeed; she is leaving nothing undone to get herself elected president of the sewing society. —*Chicago Inter-Ocean.*

ANCIENT COQUETTE—What, you are a major already? How time flies! Do you remember how often you used to play with me when I was a little girl? Major —That was my father. A. C.—Oh, no. Major—Then 'twas my grandfather.— *Fliegende Blaetter.*

"Do you believe that contentment is better than riches?" "Perhaps so, if you have them both together."—*Chicago Inter-Ocean.*

Address all communications to P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A.M., M.D.
Editor.

PENFIELD PUBLISHING COMPANY
Publishers.

Editorial Offices, 1026 Arch Street, Philadelphia, Pa.

Entered as second-class matter at Asbury Park, N. J.

TERMS:—Three Dollars a year in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publishers, and should be made by Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to inclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, DECEMBER 29, 1894.

EDITORIAL.

A BALANCE SHEET.

The current number completes the seventy-first volume of THE MEDICAL AND SURGICAL REPORTER and ends the forty-second year of its consecutive publication.

1894 will be notable in the records of science as a medical year. The remarkable development of surgery during the few years past has obscured to a considerable degree the progress of medical research. The dazzling reports of brilliant results aroused a furor for operating which amounted to an indiscriminate craze. As experience dispels the fanciful, sound judgment discerns the fact from the factitious and, the ebullition of gas subsiding, reveals what is of genuine value and abiding usefulness. Modern surgery can accomplish wonders, but it is now settled that laparotomy is not essential for the relief of acute indigestion, nor is trephining indicated for globus hystericus. As an *applied* science modern surgery is more than ever an art requiring masterly skill and scrupulous training.

Although there have been occasional proclamations of great operative inventions or of revolutionary "modifications" or improvements, as a rule such procedures have proved merely the sky-rockets of surgical pyrotechnics, whose brilliancy vanished long before their explosion was evidenced by report, and professional attention has been diverted to the equally important if less conspicuous field of scientific medicine.

In hygiene and public health measures, protective and preventive, advances are evident.

Independent of business enterprise, and sometimes in spite of it, there has been progress in the province of therapeutics. Of the multitude of new remedies clamorous for trial and subjected to test, some have proved useful, some useless, the majority remaining on trial.

"Of the making of books there is no end," thanks to the prevision of generous publishers, and the literary crop of the

year contains some wheat among the tares. A few works have been issued in special lines whose value justifies their existence. For pronounced excellence, general utility and widest application, Dr. Gould's new medical dictionary deserves specific mention among the publications of 1894.

Most notable, however, is the prominence obtained by the applications of inductive medicine—inductive, if treatment based upon premises deduced from the observations of experimental researches conducted in the laboratory and upon the lower animals may be called inductive. In this new departure bacteriology has ruled supreme.

Bacteriology has developed with marvelous rapidity, and for a recent comer has been allowed undue importance. It did not spring into existence a full-fledged science. Its development is in truth but an enlargement of its field of work and an increase of its store of accumulated observations. As yet its data are barely sufficient for working hypotheses. Beyond establishing facts of unknown relevancy, it has proved nothing save by inference. Thus far it has not been able to demonstrate beyond very reasonable doubt the truth of its cardinal dogma, the microbic origin of disease. It has shown enough to admit of the general acceptance of the germ theory as a matter of conviction. But conviction is not proof in a scientific sense.

However incompetent to dictate, bacteriology has been of incalculable value to medical science. It has thrown light on obscure conditions; it has secured the solution of difficult problems; it has suggested possibilities heretofore undreamed and it has inspired determination to realize the possible.

To-day the entire world is anxiously awaiting the decision of medical science as to the value of the latest product of bacteriology, the antitoxine treatment of diphtheria. Unfortunately the reports of this treatment are so uniformly and enthusiastically favorable as to arouse grave suspicion of reliability. It will be well to observe the results of the procedure in the hands of American practitioners and in this country, before selling all possessions and sending the cash abroad to secure this alleged pearl of great price. Tuberculin bubbles are very costly, both in money and in self-respect. Moreover, what the new treatment may have of genuine utility will have been demonstrated by European experience by the time properly prepared serum is available for general use here.

Other novelties of undetermined value have been presented for professional assay, among them the "animal extracts" and nuclein therapy.

Medical associations have flourished with increasing vigor, and the most valuable contributions to medical literature lie scattered throughout society "transactions."

The balance sheet will show a year of much profit to medical science.

For Ringworm.

Iodine has been found to be one of the most effective agents for destroying the parasite upon which this disease depends. An excellent method of applying it is the following: Thoroughly cleanse the scalp with soap and water. Dry perfectly, then apply a solution of one part of pure iodine in thirty parts of flexible collodion. Renew the application each day for four days. At the end of fifteen days remove the collodion, wash the scalp first with soap and water, then, after thoroughly removing the soap, wash with a hot solution of bichloride of mercury, one-twenty-five-hundreth. After allowing the bichloride solution to remain in contact with the scalp for half an hour, wash with pure water, dry, and apply vaseline or zinc ointment. If necessary, repeat the application.—*Mod. Med.*

YOUNG HUSBAND—Amy, what makes that baby yell in that way? Young Wife—His teeth, dear. Young Husband—Oh, if that's all, I'll run for a dentist and have them pulled out.—*Boston Home Journal.*

ABSTRACTS.

A CASE THAT OUGHT TO HAVE BEEN ONE OF RAILWAY SPINE.

The subject of "railway spine," or "injuries of the cord and its envelopes without fracture to the spine," has been of such intense interest of late to the railway surgeon that much of the time allotted to one convention of railway surgeons has been devoted to this subject and its discussion. So much has been said pro and con that one is sometimes in doubt if such a disease really exists, and in some cases, in order to produce the disease after the injury, supposed or real, has been received, it is necessary that "suggestion" should be brought into requisition, and in the absence of this suggestion the disease often fails to materialize even after quite severe injuries. The most atrocious experiments to establish the true nature or condition of so-called railway spine, or to establish the fact that such a disease does or does not exist, have recently been practiced on dogs and other dumb animals, the recital of which makes the blood of the Berghites run cold at the excessive cruelty of the means employed in the experimentation; but as yet nothing seems to have been definitely settled, either as to the nature of the disease, real or imaginary, or as to the treatment of this condition. It seems, however, that the one word "suggestion" is needed to give shape and form to this disease, no matter what the injury may have been in the first instance. Webster says of suggestion: "It is a hint, a first intimation, proposal, or mention;" second, "a presentation of an idea to the mind, as the suggestion of fancy or imagination;" third, "insinuation, secret notification or incitement;" fourth, in law, "information without oath." Hence we see the nature of suggestion and are able to determine in some measure the effect it may have on the mind. Now as nearly, if not quite, all these cases of "railway spine" occur near large towns or cities, or among those who live in them, it is safe to suppose that those developing them have received from the wiseacres and interested persons the necessary suggestion that they are so badly injured that they must certainly be paralyzed or that they will be permanently damaged, and they can get a snug sum out of the company if they will only bring suit on that ground; and if no counter-suggestion is offered that would annul the suggestion the suit is often successful, and the railway company frequently unjustly mulcted out of a large sum of money to settle the so-called damages.

Illustrating this subject, a case with the detail of circumstances will be given, which occurred in the practice of the writer about two years since, a case that certainly ought to have been one of railway spine, and as it is one so well suited for the illustration of this as well as of another subject which has engagad the attention of railway surgeons, viz., of the power which whisky seems to have to prevent shock, it is here given as being of double interest.

Bert M., a high-toned tramp of local reputation, having already "a good jag on," started out in quest of another "load," which he expected to get in the adjoining town, and took the railway track as his highway. He had not gone far, however, before the load he was already carrying became too heavy for him. It being Sunday, a day of rest, he laid him down to sleep on the railroad track, and being very drunk his sleep was profound. For further description of the incidents as they occurred I cannot perhaps do better than to quote from a letter I received from a railway official who was an eye-witness to the occurrence and was riding on the engine at the time:

"Dear Sir: Replying to your favor of —— date relative to our engine on the Devil's Lake special striking Bert M. on September 11, 1892, I have to say that the train was running about forty miles per hour when Engineer William C. discovered a dark object laying on the track at a wagon-road crossing, which he supposed to be a dog until he got close to it, when he discovered that it was a man lying down with his legs at right angles with the track and his body parallel and on top of the rail. He was lying on his left side with the lower part of his body toward the on-coming train. The 'pilot' being low struck him square on

the rump, knocking him clear off the track into the ditch, his only injury appearing to be a badly skinned face, caused by sliding on the gravel after being struck. He was very drunk and did not move when the engineer sounded the whistle. He had to be helped on the train, which was done without difficulty. He was quite peaceable, except swearing at the engineer for waking him up and making such a noise. On our arrival at Tecumseh he had sobered up sufficiently to get off the train and walk into the depot without assistance. The train was running at the rate of about ten miles an hour when it struck him." Here is a case of a man being struck in the back or, as the narrator terms it, on the rump, by a ponderous locomotive and train running at the rate of ten miles per hour, throwing him into the ditch like a cow or hog, but being braced up with very liberal libations of whisky, shock seemed to have been prevented. He was seen by the writer within an hour after the accident, but not until some one had given him the suggestion that he would probably be paralyzed and that he ought to sue the company for damages. On examination it was found that the face was badly skinned on the left side and over and about the left eye, also that the back was badly bruised over the dorsal and lumbar vertebræ. He complained of numbness in both legs and feet, and it seemed difficult for him to stand or walk. Full doses of ergot were prescribed for him, and an occasional dose of bromide of potassium. He was sent to his home, four stations distant, the same afternoon, with instructions to follow up his treatment as long as his medicine lasted and to apply frequently along the back a lotion of arnica and whisky, which was given him, the arnica being added to prevent him from drinking the whisky and the rubbing to keep him active and his mind engaged. In about a week the writer received a letter from this patient, offering to "whack up" and divide the profits if he could get assistance from this source to help him win his suit. He was at once informed by letter that the company was in no way responsible for his injuries and that it was very certain he could never gain anything from the company by suit, and that the very best thing he could do would be to "brace up" and get well just as quickly as he could.

Here was the counter-suggestion, which had its effect, for the man made a rapid recovery and was perfectly well in ten days, although claiming that he was completely paralyzed at the time his letter was written asking for assistance to "go in" with him and sue the company for damages. Upon careful investigation only a few weeks since it was ascertained that he has remained perfectly well ever since. The only treatment employed in this case was as before stated.

It is not urged that cases of railway spine do not exist or that serious and fatal injuries do not often occur involving the spine, but it is believed that cases of so-called "railway spine" are far more frequent than they should be, resulting from the class of injuries that are said to produce them, *i.e.*, concussion or succussion of the cord occurring in collisons and derailments without any bruising or crushing injury, and that very many of these cases are of malingering, which may often be cured by a counter-suggestion from the surgeon and but very little simple treatment, and it is proper for surgeons to be on their guard for just such cases.

To go into a minute description of the anatomy of the spinal cord or of the pathological conditions that may exist in cases of so-called "railway spine" is not within the scope of this paper. It is believed, however, that if the surgeon will offer the counter-suggestion with sufficient firmness many cases of traumatic neurosis that now come under our care would be avoided, with great relief to the surgeon, the patient and the railway companies.—*Dr. Woodward in Railway Age.*

Chloroform Nausea.

With regard to chloroform nausea, too little regard is paid to prophylaxis. In the case of sea-sickness nothing is so important as treatment of the stomach before the voyage; and nothing will prevent chloroform sickness like careful dieting and some compound rhubarb powder during the three days preceding operation. In emergency cases washing out the stomach before operation would be most useful. To treat the nausea, absolutely nothing by the mouth, except perhaps a few drops of acidulated ice-cold water to relieve the dryness of the mouth itself, and copious, faintly saline enemata to relieve thirst, though stern treatment from the patient's point of view, is the shortest and best road to relief.

CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISON J. MORRIS, M.D., AND SAMUEL M. WILSON, M.D.

IN THE BUFFALO MEDICAL AND SURGICAL JOURNAL

for December, Dr. George E. Clark writes on

Hydrotherapy in Appendicitis.

In articles on appendicitis the use of water is recommended only for the purpose of opening the bowels, but the author has found great benefit from the systematic use of cold-water enemata when the bowels were not inactive.

A series of seven consecutive cases is given, all of which had "localized pain in the right illiac fossa, induration or tumor, McBurney's tender point, fever and furred tongue. Some had vomiting, all had diarrhœa or constipation, or diarrhœa followed by constipation." (Corresponding to Osler's definition of symptoms).

These cases received no medicine except in a few instances where an initial dose of phenacetine was given. All received enemata of cold water at intervals varying from every hour to three times daily and had wet cold compresses applied over the tumor. The rapidity of cure bore a certain relation to the number of enemata given, but the innovation was so strongly objected to by the families of some of the patients that in these instances only two or three injections daily were given. The treatment was usually continued five or six days.

The author states that he does not think this method will cure every case, and thinks operation is necessary in some instances, but some of the cases reported seem to have reached a point where no choice was left before being seen by him.

The probable explanation of this effect of cold water, the author thinks, lies in the fact that the vessels of the rectum and sigmoid flexure are secondarily dilated and actively withdraw blood from the inflamed cæcum.

Dr. A. A. Young writes of

Some Points in the Etiology, Pathology and Indicated Treatment of Diphtheria.

The author regards the disease as primarily a systemic one, and thinks local treatment of the throat as ineffective as the local treatment of a chancre would be (thinking both diseases systemic before locally manifest).

The swelling of the cervical and submaxillary glands he thinks an important diagnostic symptom, as it should be manifest at least as soon as the membrane.

Mechanical obstruction of respiration by membrane is not believed in, but these cases are regarded as primarily due to paralysis of the (general) respiratory nerves; therefore tracheotomy is not advocated in such cases.

The treatment will probably be the use of antitoxine and toxalbumen; but at present pilocarpine is given to increase elimination of poison, corrosive sublimate; not, he expressly states, as a germicide, but to increase the red-blood corpuscles, and sodium chloride, papoid, etc., to assist digestion. Permanganate of potash is used as a gargle as a concession to popular prejudice.

The members discussing the paper thought the disease primarily local, with systemic infection secondarily, tracheotomy was thought to result in the cure of a fair proportion of cases of threatened asphyxia, and the antitoxine treatment was mentioned as a promising one.

Dr. Lawson Tait gives

A Criticism of the "Germ Theory of Disease" Based on the Baconian Method.

The author claims that antiseptic drugs are being relied on without the free ventilation that should accompany them. The results in certain hospitals show that overcrowding and consequent lack of ventilation still give large mortality records, in spite of the use of germ-destroying drugs.

THE SANITARIAN

for December publishes an article on

Drinking-Water and its Relation to Malarial Diseases,

by Dr. Richard W. Lewis.

The author became convinced that since the plasmodium malariæ has been proven present in malaria, this disease must be due to some substance swallowed. The plasmodia are very common in surface water, and personal experience proved that however much he was exposed to mist, night air, etc., he escaped malaria so long as he swallowed none of the surface water.

A number of circulars were sent to physicians and others living in malarial regions, asking for their experience with this disease in relation to drinking-water. The replies varied, but the majority showed that the writers thought the exclusive use of cistern or artesian well water was a decided preventive of malarial infection.

Other papers in this issue are "The Discoverer of the New Specific for Croup and Diphtheria," by Dr. C. W. Chancellor; "The Examination of the Milk Supply for Tuberculosis in the State of New York," by Dr. F. O. Donohue; "Administration of the Medical Law of the State of New York," by Dr. H. M. Paine.

THE JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for December. Dr. F. J. Tower writes of

Gouty Deposits of the Testicle.

The author uses the term "testicle" to mean the cord, epididymis, tunics, etc., excepting only the scrotum.

No literature bearing directly on this subject has been discovered by the writer, although various authorities in writing of gout mention epididymitis, orchitis, urethritis, etc., as being sometimes directly due to this disease.

In the cases reported the gouty diathesis was readily proven, uric-acid crystals were obtained once or twice from hydrocele fluid, and there had been no venereal disease. Passing an exploring needle down to the deposits elicited a grating sound, but caused no pain excepting that due to piercing the skin.

The predisposing causes seemed to be (1) an unsupported varicocele; (2) a newly married young man indulging in excessive coitus; (3) a direct inguinal hernia poorly supported by a truss.

No special treatment is advocated, and the prognosis depends on the size of the deposit and the tendency to recurrence of attacks of gout.

Dr. A. L. Gnichtel reports a

Case of Diphtheritic Vulvitis in a Child.

The child was one year old and lived in a house where two fatal cases of diphtheria had recently occurred. The internal labial surfaces and the urethral orifice presented diphtheritic membrane when examined on the fifth day of the child's apparent indisposition.

Bacteriological examination confirmed the diagnosis. The constitutional symptoms developed and the growth disappeared under washes of peroxide of hydrogen and bichloride solution.

Dr. Hermann Goldenberg writes of the

Modified Thompson Test for Urethritis Posterior.

Thompson's test is the examination of the first and last of the urine passed by a patient, collected in separate glasses. It was supposed that if posterior urethritis existed "threads" would be found in both portions; otherwise only in the first.

This having been shown to be unreliable, it was proposed to wash out the anterior urethra with clean water. Then if any pus or threads passed in the urine the posterior urethra would be proven involved

Lohnstein, of Berlin, criticises this method, claiming that the fluid from the anterior urethra is forced back past the cut-off muscle into the posterior portion, and proved by the Prussian-blue test that this might occur.

The author admits this criticism, but showed, apparently, that this was only the case if an eyed catheter was used in irrigation, a counter current forming around the eye of the instrument. The method he uses is the introduction of a short glass or hard rubber tube as far as the fossa navicularis, withdrawing a little and then irrigating. Using the ferrocyanide solution in this way and then carefully washing the glans and the prepuce, the blue reaction was not found. He therefore thinks this method perfectly reliable.

Dr. James C. White reports a case of

"So-Called 'Angioma Serpiginosum.'"

The patient is a boy twelve years old, subject to an eruption occupying a belt three inches wide, extending from the right shoulder blade to the nipple.

At birth there was noticed a purplish-red mark, half an inch in its longest diameter, situated near the right scapula. This increased in size until he was four years old, when a second smaller one appeared and since then others.

These spots begin as bright red, slightly elevated points, which gradually increase until they are from an eighth to one-sixth of an inch in diameter and an eighth to one-twelfth of an inch above the general surface, firm in consistence, and partially disappear from long pressure

These now undergo involution in the center and continue to spread peripherally, losing their regular shape by contact with similar lesions. The central skin retains a purplish color, but otherwise resumes its normal characteristics.

An attempt was made to destroy this growth by Paquelin cautery, but eventually it spread beyond the resulting cicatrices.

Examination microscopically by two experts of a couple of lesions excised for the purpose showed toward the middle of the section a lesion occupying the whole of the derma, consisting of a mass of cells more or less sharply defined at the margins, which are festooned or drawn out into angular trails which seem to form a network by ramification.

The epidermis is unaffected; the papillæ elongated, but not penetrated by the cells; but in the subpapillary stratum there is a nearly continuous layer of these cells. In the corium are to be found streaks, or ovoid masses, parallel to the fibers, and deeper on the border of the hypoderm the masses are abundant and seen in contact with the glomerulus, but never invading the tubes of the gland.

These cells are found to be young connective-tissue cells, and have an evident tendency to group themselves concentrically about centers made up of cells attached at the edges to form a canal.

Being a non-inflammatory new formation of connective tissue, this deserves to be classed as a sarcoma, and the microscopist furnishing the report proposes the name sarcome angioplastique reticule.

American observers examining the other sections compared the tumor to angiosarcoma, without declaring them identical.

Treatment of Impermeable Strictures of the Urethra.

The difficulty that is frequently encountered by surgeons in penetrating very tight urethral strictures has suggested a method of dilating them which others may find of service in their practice. It consists in passing down to the site of the stricture a catheter shaped as a simple cylindrical tube, open at both ends—an ordinary catheter from which the eyed end has been cut off and the edges carefully smoothed does very well—and through this as a guide, introducing the largest instrument, from a filiform bougie upward, which can be made to penetrate the stricture.—*Charles H. Wade in Lancet.*

PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M.D.

MEDICINE

The Value of Chloroform in Internal Medicine.

We are so apt to regard chloroform as a pure anæsthetic when taken by inhalation that many of us are wont to overlook its value as an internal medicament, and as a result of this oversight lose a valuable aid to treatment in many affections, some of which are apt to obstinately resist the ordinary remedial measures. One of the most important applications of chloroform is its internal use for the relief of pain either in the chest or abdomen, pain in the latter region yielding naturally more readily to its influence. Particularly is this the case where the pain is of a griping character, either due to irritability of unstriped muscular tissue in the wall of the intestine or to the presence of irritating foods or large quantities of flatus. Under such circumstances twenty to forty drops of the spirit of chloroform added to two tablespoonfuls of water and perhaps aided by ten to twenty drops of the spirit of camphor is one of the very best prescriptions that we can give. Further than this, those of us who believe in the value of antiseptic medication will recognize the fact that chloroform, under the circumstances which we have named, not only relieves the pain, but acts as one of the most powerful antiseptics which can be taken internally with moderate impunity. It is a well recognized fact in therapeutics that many volatile substances seem to exercise very considerable power in checking all forms of watery diarrhœa, and where pain in the abdomen is associated with liquid movements chloroform possesses a third scope for usefulness. Not only is it of value in the forms of pain which are due to direct irritation or inflammation in the abdomen, but it is also useful in those pains which are due to nervous disturbance, such, for example, as in ordinary neuralgia of the stomach or true gastralgia. In obstinate vomiting, two to five drops of pure chloroform in a little water, taken in teaspoonful doses, will often act advantageously, and when the vomiting is due to the ingestion of bad food, particularly food which has undergone some decomposition process, it is especially indicated. In the vomiting of pregnancy, with some practitioners, it is held to be the best remedy. Another very valuable application of chloroform is its employment externally in liniments in cases of muscular rheumatism for stiffness of the muscles due to strain or excessive exercise. Possessing as it does not only counter-irritant, but anæsthetic effects, its employment in this manner is most advantageous. Another use to which it is too rarely put is for the production of counter-irritation varying from slight reddening to actual blistering of the skin. Slight reddening is rapidly produced by applying a cloth saturated with chloroform to some portion of the skin so remote from the respiratory apparatus as to avoid inhalation in any large quantity, and the blisters may be formed by placing chloroform on the skin under a watch-glass, so that too rapid evaporation will not take place. For those who are unable to take opium in any combination for the relief of pain in any part of the body, a prescription composed of thirty drops of spirit of chloroform and ten minims of the fluid extract of a good cannabis indica is a valuable prescription.—*Ther. Gaz.*

Chloroform During Sleep.

The following case is of interest as bearing on the question whether a sleeping person can be chloroformed without awakening. The reporter was asked to take two teeth out for a girl aged seven, and as she is very timid and excitable, to give her chloroform. On going to her home he found her lying on her back in bed, sound asleep. Having poured about two drachms, probably more, of chloroform on a folded towel, he gradually brought it to about two or three inches from her mouth and held it there. She went on breathing quite quietly, and neither coughing nor making any unwonted movements. In a very short time she was so well under its influence that her hand fell down when raised and the conjunctiva was insensible to touch. She was then lifted out of bed, carried into another room and laid on a sofa without her giving any sign of consciousness. On opening her mouth, however, she put up her hands and turned her head on the pillow. More chloroform was given, and almost immediately she was in a state of complete anæsthesia and the teeth were extracted. She was easily aroused, but almost momentarily fell again asleep and slept for two hours. When she awoke she was much astonished to find that her teeth were out.—*Ther. Gaz.*

Turpentine Vapors and the Elimination of Uric Acid.

Benoit du Martouret (*Lyon Medicale*) gives the details of two cases—one of arthritism accompanied with right crural neuritis and cardiac arterio-sclerosis, and the other of pyelo-nephritis of calculous origin—in both of which dry turpentine vapor baths produced satisfactory results by distinctly increasing the elimination of uric acid. For these baths the fresh resin of the *pin mugho* was used. In view of the results obtained, the author suggests that cases of pyelo-nephritis due to the presence of calculi might be cured by the treatment alluded to. This will in time so reduce the size of the calculus that it may with ease be voided through the natural passages.

Dr. Brown-Sequard's Orchitic Fluid.

The death of Dr. Brown-Sequard has served to revive in some minds an interest in his orchitic fluid, in which the great physician had himself much hope. The *Lancet* in a recent number publishes some significant notes upon experiments with the fluid made by Dr. Guy M. Wood and Dr. A. J. Whiting, both physicians to the Hospital for the Paralyzed and Epileptic, Queen's Square, London. The fluid was obtained directly from Paris; through Dr. Brown-Sequard's personal kindness. The injections were hypodermic, made with a Koch syringe, kept aseptic in absolute alcohol. The dose was from one gramme of the fluid to six grammes, and in all but three cases diluted with an equal quantity of water. Except when the doses were large, no immediate effects were perceptible. In those some pain was felt at the point of injection. Twenty-three patients were treated. In 18 cases there was no change from the treatment; 3 patients were slightly better; 2 were worse. At the beginning of the observations several patients said they felt better after the injections. At the suggestion of Dr. Buzzard, two women were given daily injections of two grammes of distilled water only for three weeks. Both the patients declared that they felt decidedly better after each treatment, though of course there was no change in the physical condition. The physicians, therefore, conclude that in all the cases treated the sensation of being better was due to the mental effect of the injection and not to the orchitic fluid, and they do not think that the results obtained warrant any further trial of the remedy.

Hydrastinine in Uterine Hemorrhage.

According to Kallmorgan, who has treated during two and a half years 100 patients with hydrastinine, the best results are obtained in the cases of hemorrhage following hematocele, 100 per cent. being cured; in simple menorrhagia, 85 per cent.; in hemorrhage after abortion, 83 per cent.; and in hemorrhage dependent upon disorders of the tubes and ovaries, 75 per cent. Less satisfactory was the treatment of chronic endometritis, and little or no influence of the drug could be observed in cases of hemorrhage during pregnancy or arising from myoma and carcinoma. The remedy was administered by the mouth in the form of pill, the dose varying from one-half to one grain three times daily. The by-effects were only slight—occasional stomach-ache or nausea. No other therapeutic treatment accompanied that with hydrastinine.—*Med. Chronicle.*

Menthol in Diphtheria.

F. Kastorsky (*Brit. Med. Jour.*) reports 37 cases of diphtheria (in 3 adults and 34 children) treated and cured by painting with a 10 per cent alcoholic solution of menthol. The paintings (by means of a piece of cotton wool) were usually carried out three times daily. In some cases, however, a single free application was followed by a complete disappearance of false membranes within two days. A marked improvement in the patient's general condition was invariably noticed from the beginning of the treatment. The same simple method was successfully practiced by the author in numerous cases of anginas of various forms, and by Trutovsky in a group of cases of scarlatinal diphtheria.—*Maryland Med. Jour.*

SURGERY.

Hydrotherapy in Fractures.

More than twenty years ago the writer adopted the practice of treating fractured limbs for a short time with various applications of water before putting the parts into a permanent dressing. By this means it is found possible to avoid much of the pain, swelling and discomfort which the patient usually suffers during the first few days after the application of the dressing, and to secure more speedy and complete union, with less disability of the overlying muscles and the contiguous joints. We have frequently found hot fomentations most useful in these cases. The application of hot fomentations, or soaking the affected parts in hot water for an hour or two, almost invariably has the effect to relieve pain from circulation in the contused vessels, to prevent swelling, to overcome muscular spasm and rigidity, and to promote the recovery of the patient. If there is much displacement of the fragments it is, of course, important that the parts should be drawn as nearly as possible into position. The parts can be retained by a temporary pasteboard splint and light bandage during the application until the permanent dressing is applied. Dr. T. Morton, of Philadelphia, recently reported a case (*New Eng. Med. Monthly*) in which an ununited fracture of the leg was made to unite three or four months after the accident occurred by applications of hot water and massage.—*Mod. Med.*

Fin de Siecle Treatment of Gonorrhœa.

Among the numerous suggestions on the treatment of gonorrhœa with which the medical press abounds, none has appeared which is so entirely unique as that presented by Dr. Burnside Foster in a recent issue of the *Journal of Cutaneous and Genito-Urinary Diseases.* The method proposed is described as follows by the author: "As soon as may be after we have established the diagnosis of a first gonorrhœa, the patient should be etherized and properly prepared, a button-hole opening made in the perineum and drainage of the bladder established. Through a properly contrived apparatus the anterior urethra could then be thoroughly flushed with any antiseptic or cleaning fluid and treated on surgical principles. The details of the local treatment would vary with the fancy of the operator. The feasibility of packing and distending the anterior urethra with iodoform gauze suggests itself to me; but any one of a great number of methods would doubtless be efficacious."

Functional Troubles Following Old Fractures of the Patella.

After a careful study of this subject Choux (*Rev. de Chir.*) comes to the following conclusions:

1. The functional troubles consequent upon old fractures of the patella are either insufficient extension or flexion.

2. The difficulty in extension is due less to the atrophy of the triceps muscle than it is to the momentary physiological inability of the muscle to act efficiently upon the lower fragment of the patella.

3. The difficulty in flexion is dependent on the fibro-articular thickenings, which are themselves due to the retraction of the patella tendon and to the method of union between the fragments.

4. Of the five modes of union, as generally divided, two types alone are capable of interfering with flexion; they are the short but stiff osseous or fibrous union and the fibrous union with 2 to 5 cm. separation of the fragments.

5. The prognosis in incomplete extension may be doubtful for several years, but restoration of function is generally the rule. Intraosseous suture of the fragments is indicated in cases where the spontaneous re-establishment of function is not realized after a reasonable length of time.

6. In regard to partial ankylosis resulting almost always from short, rigid union between the fragments, either osseous or fibrous, but increasing the length of the patella 2 or 3 cm., he considers the removal of one of the two fragments the only possible means of overcoming the functional difficulty, unless these types are transformed, as often happens, into types more favorable to flexion.

7. The articular inflammatory thickenings, which often disappear, should be held under observation for from twelve to fourteen months, and are eminently fitted for the hydrothermal treatment as used in the hospital of Bourbonne.—*Amer. Jour. of the Med. Sci.*

Cautery for Furuncle.

Loewenberg (*Bull. Medicale*) recommends to abort furuncle the employment of the galvanic cautery, using a fine platinum point, 1 cm. long and not over 1 mm. in diameter. When the developing furuncle is recognized by a light area surrounding one of the hair follicles and special sensitiveness to the touch, the cautery point is brought to a white heat and is thrust into the center of the areola deep enough to reach the bottom of the hair follicle, and is left there an instant in that position before it is withdrawn. He has especially applied this method to the furuncle of the ear, and claims for it a prompt action in checking the formation of new centers of inflammation.

New Means of Local Anæsthesia.

One Dr. K. L. Schleich, of Austria, claims to have discovered that absolute immunity from pain, even during protracted operations, may be obtained by subcutaneous injections of a sugar or salt solution, or of merely cold distilled water; that the results induced are to all intents and purposes identical with those obtained by like employment of cocaine. He adds:

The patient may remain perfectly conscious during the amputation of hand and foot without undergoing the tortures so often inflicted upon the battle-field or the exceptional dangers of syncope ever present in the operating-room when general narcosis is resorted to.

It is declared that this discovery has already borne the test of several experiments and is about to be applied in the hospitals of Vienna. The explanation of the phenomenon is:

Local insensibility to pain is induced in the case of cocaine by purely chemical changes, while cold water and solutions of sugar and salt act mechanically through high pressure and low temperature. Under the influence of high pressure and sudden low temperature the blood and lymph are driven from the places operated upon to where the pressure is less. The tissues are thus deprived of their supply of blood and temporary paralysis of nerves results.

The foregoing seems to have met with favor in numerous quarters, and in one instance at least a surgeon of authority affirms that "its importance is all the more undoubted, seeing that if in a given case cold water alone should fail to produce the needful degree of insensibility, a weak and absolutely harmless solution of cocaine would prove certainly efficacious."

Whether true or false, it is hardly probable that surgeons will give up the use of cocaine, which is deemed certain, in favor of a method which will always be apt to carry with it a feeling of indefiniteness.—*Medical Age.*

Treatment of Pruritus Ani.

Dr. A. Berger states that the following method immediately relieves the itching and causes a rapid disappearance of the eczema of the perineum and scrotum which frequently exists in these cases: A cotton pledget 2 or 3 cm. ($\frac{3}{4}$ to $1\frac{1}{2}$ inches) in length and steeped in a 2 per cent. solution of hydrochlorate of lime is introduced into the anus. This pledget is allowed to remain until there is a slightly smarting sensation, when it is immediately withdrawn and the anal region washed with the same solution, taking care not to wipe it off afterward.—*Intern. Jour. of Surg.*

Chronic Hernia.

Dr. Bishop (*Lancet*) states:

1. That chronic and acute hernia are absolutely different things, agreeing only in the fact that they are both protrusions of viscera through their normal environments.

2. That they differ in etiology, pathology and course.

3. That, especially from the point of view of radical cure, it is important to distinguish between them.

4. That in discussing the feasibility of operations for radical cure, and especially the permanency of their results, the etiology of chronic hernia is of immense importance, since an operation for the cure of the results of the cause is almost certain to be useless while the cause remains in operation; and if the cause can be found, the patient may be moved to avoid it after the operation has been performed, in order that permanency may be rendered more probable.

5. That in the case of chronic hernia the cause is never one acting suddenly and singly, as overlifting, strains, falls, etc., but always acting slowly, persistently, gently, habitually (such causes are difficulties in urination and defecation, certain occupations, and, chiefly and most prominently, coughing in all its forms).

6. That the claims of any operation for radical cure of chronic hernia cannot at present be properly estimated, and that they never can be unless acute and chronic hernia are absolutely separated and the true effective causes of them are duly appreciated, other causes being previously carefully eliminated.

Renal Section in the Treatment of Certain Forms of Anuria.

At the meeting of the French Surgical Congress M. Picque, of Paris, said: "A woman having an inoperable cancer of the womb suffered for thirteen days from an absolute anuria which at last was accompanied by œdema and vomiting. The left kidney was of increased size. The anuria was evidently due to compression of the left ureter with reflex paralysis of the right kidney. I incised the left kidney and packed the wound with iodoform gauze. The urine escaped by this route and the symptoms of uræmia disappeared. The kidney was healthy. The patient's life was by this operation prolonged for several months, and the right kidney resumed its functions. Three years ago M. Pozzi had performed a similar operation in a case of obstruction of the ureter in consequence of a vaginal hysterectomy. The results were very satisfactory."

M. Broca stated that in a case of cancer of the bladder, simulating exactly a calculus of the left kidney and diagnosticated as such by M. Guyon, he had incised the organ and found the kidney healthy. The secretion of the urine by the right kidney was re-established, the loss of function upon that side having been reflex and dependent upon obstruction of the left ureter by the cancer. The patient was benefited by the error of diagnosis, and the results corresponded with those obtained by M. Picque.—*Le Bulletin Medical.*

OBSTETRICS.

Hemorrhage in Pregnancy.

Cases are by no means rare where slight hemorrhage, or something resembling menstrual flux, occurs at the time for the regular catamenial period for the first two months of pregnancy, and in some cases extends during the entire period. This condition does not necessarily indicate placenta prævia, for where that exists Playfair says the hemorrhage rarely begins before the end of the sixth month, and sometimes not till labor has commenced. Depaul, in 70 cases, says in 1 case only the hemorrhage occurred before the sixth month; in 7 from six to seven months; in 12 from seven to eight months; in 26 from eight to nine months; and in 24 at term or near. A month before actual labor it is not unusual for slight pains, resembling labor pains, to occur at regular intervals, even with the slight appearance of blood. Of course in these cases the strictest rest should be enjoined and, if necessary, some remedy used to check the pain.—*N. Y. Med. Times.*

NOSE AND THROAT.

Spray for the Nose and Throat.

In Part Second of "Saunders' Question Compends," No. 14, second edition, just issued, Dr. E. B. Gleason recommends for the purpose of spraying the nose and throat the following formula: Antipyrin, grs. xvj; aquæ, fl. ʒ j.

He says: A solution of antipyrin of the above strength, when sprayed upon the mucous membrane of the nose, pharynx or larynx, has the power of contracting the capillaries and producing an artificial anemia, which effect is maintained for three to five hours. The above solution may be used with the atomizer in all acute inflammations of the mucous membrane of the upper respiratory tract. When used after the application of cocaine to the interior of the nose, it will maintain the contractile effect of that drug upon the rectile tissue for several hours; when sprayed upon the nasal mucous membrane without the previous application of cocaine, it gives rise to a smarting sensation, which, however, quickly subsides. Applied as a spray within the larynx by means of an atomizer, it contracts the blood-vessels of the laryngeal mucous membrane and diminishes secretion, cough and expectoration. It is extremely valuable as a remedy for the night cough of laryngitis phthisica, often securing a night's rest for such patients, who may be provided with an ordinary hand-atomizer filled with a solution of antipyrin and instructed to inhale its spray as often as is required to control the cough.

GYNECOLOGY.

Palliative Treatment of Uterine Cancer.

Boldt (*Archiv. of Gyn.*), speaking of cases where operation is impracticable as the malignant deposit cannot be removed entire, recommends as the best form of treatment curetting and subsequent cauterization. Curetting and packing with pledgets saturated with chloride of zinc will also prove beneficial. If rigid antiseptic precautions be

taken, piercing of the uterus by the curette may do no harm. The uterus is first curetted, then the cavity is repeatedly sponged with a mixture of commercial acetic acid (1 dram), glycerine (8 drams) and carbolic acid (20 grains). Lastl y the cavity is packed with absorbent wool.

Cauterizing Ovaries Instead of Removal of Them.

Dr. Pozzi, at Hopital Broca, has now practiced cauterization of painful ovaries for over two years, and considers the plan very successful. In one case, in which he operated upon both ovaries, the woman has since given birth to a child. He performs his laparotomies in the ordinary recumbent position; draws the ovaries out of the abdominal opening. If the ovary is totally diseased he removes it, but if a part is found to be healthy he amputates the affected portion, cauterizes the stump, then sews the end with silk. If there are some small cysts he opens them by touching with the Paquelin point. The ovary being returned to the abdomen, he examines and treats the other in a similar manner. Often as many as six small cysts are opened in this way in each ovary.—*Paris Cor. Ther. Gaz.*

Pelvic Examinations in Stout Women.

Abdominal palpation is usually not a difficult procedure in thin women with flaccid muscles, but in the stout it is not an easy matter to map out any condition of the uterus or ovaries. Dr. Harris A. Slocum explains in the *Philadelphia Polyclinic* a method of palpation to be used in the most obese. He has noticed even in the stoutest women a narrow zone where the fat in the abdominal muscles is very spare and through which examinations may be made with the greatest satisfaction. The fat on the abdominal wall is thickest in the region of the umbilicus, thinning off toward the flanks.

Here, he says, a careful examination will show in any woman a depressed, curved line running from one anterior iliac spine to the other, with its convexity toward the mons veneris. At and near this groove little fat will be found. By placing the finger-tips in this groove and depressing, the abdominal organs may be felt and the fat may be pushed before the hand and kept out of the way. In intestines distended with gas or when the corset or dress is tight, this manipulation cannot be well carried out. Everything should be loosened and the most comfortable position assumed, when the examination will be much easier than usual in stout women.

PHYSIOLOGY.

The Process of Going to Sleep.

"Order is heaven's first law," and the truth is manifested even in the process of going to sleep. When a man drops off to sleep his body does not do so all at once, so to speak. Some senses become dormant before others, and always in the same order. As he becomes drowsy the eyes close and the sense of seeing is at rest. It is quickly followed by the disappearance of the sense of taste. He next loses the sense of smell, and then, after a short interval, the tympanum becomes insensible to sound, or rather the nerves which run to the brain from it fail to arouse any sense of hearing. The last sense to leave is that of touch, and in some hypersensitive people it is hardly ever dormant. Even in their case, however, there is no discriminating power or sense of what touched them. This sense is also the first to return upon awakening. Then hearing follows suit, after that taste, and then the eye becomes able to flash impressions back to the brain. The sense of smell, oddly enough, though it is by no means the first to go, is the last to come back. The same gradual loss of power is observed in the muscles and sinews as well as in the senses. Slumber begins at the feet and slowly spreads up the limbs and trunk until it reaches the brain, when unconsciousness is complete and the whole body is at rest. This is why sleep is impossible when the feet are cold.—*Cincinnati Med. Jour.*

The Physiological Effects of Cycling.

The physiological effects of cycling have recently been studied by Dr. Blazhevitch, of St. Petersburg, who publishes his results in his "Graduation Dissertation" (*Med. Rec.*). He tabulates 270 observations on 104 individuals of both sexes and various ages, distinguishing between ordinary riders and those who train themselves for and ride in races or attempt to cover long distances. He finds that the play of the chest is diminished immediately after riding, especially in the cases of women and children and of men racing or commencing cycling, the diminution amounting in these cases to from 1 to 1.5 cm. In men accustomed to the exercise the effect was scarcely perceptible. The general effect of the summer's riding upon the male votaries of the sport was, according to Dr. Blazhevitch, practically nothing. In women and children the effect was slightly to increase the vital capacity. The arm power was found to have increased more than the leg power in young persons and in beginners, but in the case of men of mature age who had previously been accustomed to cycling this was not so evident. Speaking generally, the effects of cycling on the system were found to be very similar to the phenomena noticed by Tsymkovski in soldiers who had been running and by Gruzdeff and Passover as resulting from rowing.

Function of Ciliated Epithelium of the Tubes.

Dode's experiments seem to carry out the theory of Tait as to ectopic pregnancy being the result of former tubal trouble with the destruction of the ciliated epithelial lining (*Arch. f. Gynek.*). He injected an emulsion of charcoal into the abdomen of a rabbit'

and after several hours found the tubes filling with the particles of the charcoal. He then used the ova of the Ascaris lumbricoides Suis, injecting them into the abdominal cavity. In twelve hours large numbers of these ova could be seen in the tubes. This seems to prove that the ciliary currents cause ova not only to go from the ovary directly to the uterus, when the fimbriated extremity of the tubes has received it directly from the ovary, but that in case it escapes into the abdomen a like course will be taken, and uterine pregnancy is impossible if the tubes are normal.

BACTERIOLOGY.

What We Are Coming To.

(Public School, first grade, A.D. 1905.)

Teacher (to applicant for admission)—"Johnnie, have you got a certificate of vaccination for small-pox?"

"Yes, sir."

"Have you been inoculated for croup?"

"Yes, sir."

"Been treated with diphtheria serum?"

"Yes, sir."

"Had your arm scratched with cholera bacilli?"

"Yes, sir."

"Have you a written guarantee that you are proof against whooping-cough, measles, mumps, scarlet fever and old age?"

"Yes, sir."

"Have you your own private drinking-cup?"

"Yes, sir."

"Do you promise not to exchange sponges with the boy next to you and never use any but your own pencil?"

"Yes, sir."

"Will you agree to have your books fumigated with sulphur and sprinkle your clothes with chloride of lime once a week?"

"Yes, sir."

"Johnnie, you have met the first requirements of the modern sanitarians and may now climb over yonder rail, occupy an isolated aluminium seat and begin making P's and Q's as your first lesson."—*Times and Register.*

Recent Discoveries in Relation to Bacteria.

Dr. Edward Long Fox, in his admirable address as president of the British Medical Association, at its recent annual meeting, summed up some of the most important recent advances in the science of bacteriology as follows:

"It is well known now that abscesses caused by staphylococci have a tendency to remain localized, while those from streptococci are often followed by metastatic abscesses, as in erysipelas, puerperal fever and ulcerative endocarditis. We know now that the tubercle bacillus is found in chronic bone disease; and that if this bacillus exists alone, the disease is a chronic one, while if the streptococcus pyogenes is present also, the disease is more quickly fatal; that the suppurations accompanying tuberculosis are due partly to the tubercle bacillus itself, or rather to the poisons resulting from the action of that bacillus, but partly also to other micro-organisms; that the bacillus diphtheriæ is found chiefly on the surface of the false membrane, and that the fatality of that disease depends on the poison secreted by the bacillus diphtheriæ, while the presence of streptococci renders the disease more grave, the increased virulence being due to the existence of both these organisms together.

"We find that acute pneumonia is caused by the pneumococcus of Talamon-Fraenkel, although often associated with the streptococcus pyogenes. This pneumococcus, too, may produce abscesses in patients free from pneumonia, as in purulent pleurisy, ulcerative endocarditis and suppuration of the nasal fossæ. The fact that this microbe exists in the saliva of healthy people proves that these diseases have also a non-microbial element. Some condition of the sympathetic, influencing the caliber of the blood-vessels, or some morbid condition of the vagus or of the accelerator nerves, or some inherited vulnerability, with all its possibilities, must probably be precedent factors.

"The typhoid bacillus is often accompanied by other micro organisms, especially the streptococcus pyogenes or the staphylococcus aureus and albus."—*Mod. Med.*

NEWS AND MISCELLANY.

Reduced Rates for Christmas and New Year's.

The B. & O. R. R. Co. announces that excursion tickets will be sold between all stations on its lines east of the Ohio River during Christmas and New Year holidays, at reduced rates, for all trains December 22, 23, 24, 25, 29, 30, 31, and January 1, 1895, valid for return passage until January 3, 1895, inclusive.—3t

1 GHL 32f
